Introducing the NEW Mark 14 Wright respirometer

Harlake

Latest in the range of BOC Wright respirometers, this new Mark 14 has been designed to simplify procedures for measuring inspired or exhaled tidal and minute volumes in adults and children.

The re-designed movement and face presentation provides clear, precise indications of volume up to 10 litres. The large hand states volumes between 0-1 litre, graduated in .05 litre increments. The smaller hand states volumes between 0-10 litres and is graduated in 1 litre increments.

The new case incorporates inlet and outlet connections compatible with the proposed ISO standard 22 mm. connections. A new set of circuit adaptors permits complete male/female sequencing as well as connection to 15 mm. ISO tracheal tube connections.

The instrument responds to gas flow in one direction only indicated by an arrow. With this guidance, it is a simple matter to place the respirometer in circuit on either the inspiratory or expiratory side of the patient. Circuit adaptors may be used if necessary to ensure correct sequencing of connections. When placed in-circuit with a mechanical ventilator, the respirometer is normally unaffected by pressure changes.

For specifications on the new Mark 14 and other Wright respirometer models, contact your authorized Harris-Lake dealer or write to Harris-Lake, Inc.

HARRIS-LAKE, INC. A Medishield Company

new flexible Fiber Optic Laryngoscope

direct vision for difficult intubations

The first flexible fiberscope specifically for endotracheal intubations.

Portable, and with its own integral lighting system, the Flexible Fiber Optic Laryngoscope is inserted into the trachea under direct vision.

The articulating end-tip enables it to be directed into position for passage through the vocal cords. The scope then acts as a guide over which the endotracheal tube is passed.

When intubation is achieved, the scope is withdrawn leaving the tube in place.

The complete Flexible Fiber Optic Laryngoscope includes a 49 cm. flexible length, battery handle, 2 C cells, adjustable illumination, spare lamp and a special, foam-lined carrying case.

integral lighting, plus fiber optics forever eliminate "blind" intubations

1. Pass the flexible length through an endotracheal tube. The right hand controls end-tip deflection. The left hand introduces the scope through the nose, and advances it along the posterior wall of the pharynx and beyond the epiglottis.

Deflect the end-tip to see the larynx . . .

2. and pass it through the cords, into the trachea to a depth of about 5 cm.

The scope provides a clear, direct view of the internal anatomy as it travels along the respiratory tract.

3. When the end-tip is well in place within the trachea, simply advance the endotracheal tube. The scope acts as a stylet for the tube, making proper intubation a virtual certainty.

4. Remove the scope when intubation is completed.

Please rush ☐ product literature, ☐ research article reprints.

☐ I am interested also in a demonstration of the AO Flexible Fiberoptic Laryngoscope.

hi-lo® tracheal tubes*

A high volume, low pressure cuffed endotracheal tube that inflates with a minimum of air pressure. Creates a no-leak seal, usually of less than 25 cm. H_2O; avoids trauma to the tracheal wall.

Soft and pliant tubes have a true murphy tip, intubate easily. Water clear, the tube fogs on exhalation, an instant monitor of patient respiratory function. May be used orally or nasally.

Other trademarks of NCC: **holdtite™, vari-form®, ventrol®, suture rib™, versi-cath®, maxi-flex & vac™, RAE™.**

*Covered under one or more of the following patents, U.S. Pat. No's 3,625,793, 3,605,750, 3,508,554, 3,610,242, and patents pending.

†University of Pittsburgh

Ncc satin-cath™* & gluv set

This sterile, disposable gluv set has met with overwhelming acceptance.

The GENTLE-FLO® catheter has a SATIN-SLIP SURFACE™ that provides smooth, non-binding insertion into an endotracheal tube.

The paperbacked glove slips on easily, fits either hand and is easily removed when suctioning is complete. The set also contains a waterproof receptacle. Pull the marked tabs and it opens and locks in position, ready to use for the receipt of sterile water. Equipped with VACTROL® connector, catheter suction may be simply regulated from full on to off.

Available with catheters in all popular sizes. Packaged in a sterile peel-back paper pouch—50 sets/box.

pitt*† trach speaking tube

This speaking tube permits tracheostomy patients to converse. The emotional benefits are obvious.

The hi-lo® cuff inflates easily to avoid tracheal damage. This possibility is further removed because the clear tubing permits convenient bronchoscopic observation of the tracheal wall. The auxiliary air supply tube is to be connected to a humidified air oxygen outlet to achieve a speaking air flow.

Equipped with Eross Safety Straps and removable spacers and adjustable collar, the trach tube is adaptable to fit any adult patient. The suction port, which may be locked, allows for suctioning of the patient without removing the respirator and introducing a flexible fiberoptic bronchoscope, thus avoiding delays during this critical period.

Manufactured with the precision medicine must demand.

In 16 years of use in the United States, FLUOTHANE (halothane) has been administered over 100 million times in a wide variety of surgical procedures. 100 million ...extensive usage and evaluation that attests to FLUOTHANE as the most widely used inhalant anesthetic.

Since it was first introduced, over 4,000 papers worldwide have been published, ranging from review articles to in-depth studies. 4,000 papers... a bibliographic record of note on the most widely used inhalant anesthetic.

In a continuing program of inform tional services on anesthesiology, Ay provides printed and audiovisual aic reflecting the opinions and experie recognized authorities in the field include the highly regarded seri *Anesthesia Rounds* and *Clinica Anesthesiology*, as well as sev educational value—all availa your Ayerst Representative.

FLUOTHANE® (HALOTH ...OVER 100 MILLI ADMINISTRATION

- nonflammable, nonexplosiv
- permits use of high concen oxygen
- allows free use of cautery for adequate control of bleeding
- minimal odor facilitates smooth, rapid induction, reduces patient distress
- early obtundation of pharyngeal and laryngeal reflexes facilitates intubation
- lessens airway problems
- permits rapid adjustment of depth of anesthesia
- emergence is rapid and tranquil with quick recovery of protective reflexes
- minimal nausea and vomiting, shorter recovery room stay

FLUOTHANE®

brand of halothane

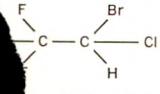
the most widely used inhalant anesthetic

from **Ayerst**

or precision, experience, quality, and service

lete text of package circular.)

tion. FLUOTHANE, brand of halo- an inhalation anesthetic. It is 2-chloro-1, 1, 1-trifluoroethane following structural formula:



gravity is 1.872-1.877 at boiling point (range) is 760 mm. Hg. The vapor mm. Hg at 20° C. The cient is 2.5 at 37° C., and er coefficient is 220 at centrations within anes- nonirritating and have a FLUOTHANE is nonflam- apors mixed with oxygen rom 0.5 to 50 per cent plosive.

does not decompose in rm soda lime. When mois- , the vapor attacks alumi- nd lead, but not copper. s soluble in rubber, some imilar materials; such ma- teriorate rapidly in contact ANE vapor or liquid. Stabil- HANE is maintained by the 01 per cent thymol (w/w), s in amber colored bottles. NE should not be kept indefi- aporizing bottles not specifically ed for its use. It is recommended at vaporizers be emptied at the end of each operating day. Thymol does not volatilize along with FLUOTHANE, and therefore accumulates in the vaporizer, and may, in time, impart a yellow color to the remaining liquid or to wicks in vaporizers. The development of such discoloration may be used as an indicator that the vaporizer should be drained and cleaned, and the discolored FLUOTHANE (halothane) discarded. Accumulation of thymol may be removed by washing with diethyl ether. After cleaning a wick or vaporizer, make certain all the diethyl ether has been removed before reusing the equipment to avoid introducing ether into the system.

Actions. FLUOTHANE is an inhalation anesthetic. Induction and recovery are rapid and depth of anesthesia can be rapidly altered. FLUOTHANE progressively depresses respiration. There may be tachypnea with reduced tidal volume and alveolar ventilation. FLUOTHANE is not an irritant to the respiratory tract, and no increase in salivary or bronchial secretions ordinarily occurs. Pharyngeal and laryngeal reflexes are rapidly obtunded. It causes bronchodilation. Hypoxia, acidosis, or apnea may develop during deep anesthesia.

FLUOTHANE reduces the blood pressure, and frequently decreases the pulse rate. The greater the concentration of the drug, the more evident these changes become. Atropine may reverse the bradycardia. FLUOTHANE does not cause the release of catecholamines from adrenergic stores. FLUOTHANE also causes dilation of the vessels of the skin and skeletal muscles.

Cardiac arrhythmias may occur during FLUOTHANE anesthesia. These include nodal rhythm, AV dissociation, ventricular extrasystoles and asystole. FLUOTHANE sensitizes the myocardial conduction system to the action of epinephrine and norepinepharine, and the combination may cause serious cardiac arrhythmias. FLUOTHANE increases cerebral spinal fluid pressure. FLUOTHANE produces moderate muscular relaxation. Muscle relaxants are used as adjuncts in order to maintain lighter levels of anesthesia. FLUOTHANE augments the action of nondepolarizing relaxants and ganglionic blocking agents. FLUOTHANE is a potent uterine relaxant.

Indications. FLUOTHANE (halothane) is indicated for the induction and maintenance of general anesthesia.

Contraindications. FLUOTHANE should be avoided when a previous exposure was followed by fever and jaundice, or when there was an unexplained postoperative fever.

FLUOTHANE is not recommended for obstetrical anesthesia except when uterine relaxation is required.

Warnings. FLUOTHANE should be used in vaporizers that permit a reasonable approximation of output, and preferably of the calibrated type. The vaporizer should be placed out of circuit in closed circuit rebreathing systems; otherwise overdosage is difficult to avoid. The patient should be closely observed for signs of overdosage, *i.e.*, depression of blood pressure, pulse rate, and ventilation, particularly during assisted or controlled ventilation.

Usage in Pregnancy: Safe use of FLUOTHANE has not been established with respect to possible adverse effects upon fetal development. Therefore, FLUOTHANE should not be used in women where pregnancy is possible and particularly during early pregnancy, unless, in the judgment of the physician, the potential benefits outweigh the unknown hazards to the fetus.

Precautions. The uterine relaxation obtained with FLUOTHANE, unless carefully controlled, may fail to respond to ergot derivatives and oxytocic posterior pituitary extract.

FLUOTHANE increases cerebrospinal fluid pressure. Therefore, in patients with markedly raised intracranial pressure, if FLUOTHANE is indicated, administration should be preceded by measures ordinarily used to reduce cerebrospinal fluid pressure. Ventilation should be carefully assessed, and it may be necessary to assist or control ventilation to insure adequate oxygenation and carbon dioxide removal.

Epinephrine or norepinephrine should be employed cautiously, if at all, during FLUOTHANE (halothane) anesthesia since their simultaneous use may induce ventricular tachycardia or fibrillation.

Nondepolarizing relaxants and ganglionic blocking agents should be administered cautiously, since their actions are augmented by FLUOTHANE.

Adverse Reactions. The following adverse reactions have been reported: hepatic necrosis, cardiac arrest, hypotension, respiratory arrest, cardiac arrhythmias, hyperpyrexia, shivering, nausea, and emesis.

Dosage and Administration. FLUOTHANE may be administered by the nonrebreathing technic, partial rebreathing, or closed technic. The induction dose varies from patient to patient. The maintenance dose varies from 0.5 per cent to 1.5 per cent.

FLUOTHANE may be administered with either oxygen or a mixture of oxygen and nitrous oxide (usually in a 50:50 ratio).

How Supplied. No. 3125—Unit packages of 125 cc. and 250 cc. of halothane stabilized with 0.01% thymol (w/w).

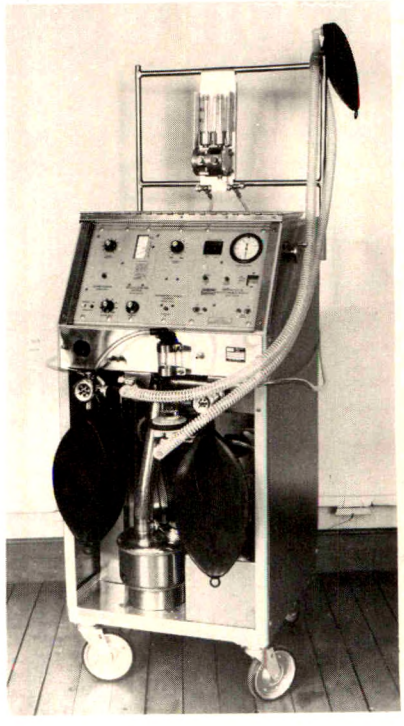
EMERSON IMV Ventilator

Intermittent Mandatory Ventilation



Continuous-flow voluntary ventilation, with intermittent forced breaths, is an alternative to assisted or controlled respiration. It has been found especially valuable for infants and for use in "weaning" adults as they improve.

Air fully humidified (and usually enriched with oxygen) flows continuously to a reservoir bag, and is available for unobstructed inspiration by the patient. A slight expiratory back-pressure (PEEP) may be added, to keep the lungs expanded. At intervals the ventilator delivers a "mandatory" breath, which supplements the patient's own breathing activity and increases minute volume. The machine does not have to "take over". The patient maintains his own homeostasis, without interference from drugs or hyperventilation.[1]

At first the ventilator is generally set to supply mandatory breaths at a normal controlled rate. This controlled respiration is then gradually changed, by lengthening the interval between breaths (a second or two at a time) as the patient's condition improves. Eventually mandatory breaths are spaced so far apart that the patient scarcely relies on them at all — and "weaning" is completed.[2]

VERSUS ASSIST

Triggering an assistor has often been a problem, particularly for infants, since their rates are rapid and their inspiratory impulses are slight. If synchronization is less than perfect, the patient inhales (at least part of the time) with no fresh gas available. Under such circumstances, blood levels of CO_2 rise, as noted by Kirby and associates.[1]

VERSUS CONTROL

For apneic patients, control is obviously needed. But to take over, when a patient is breathing spontaneously, drugs have to be used or the patient has to be hyperventilated. Either procedure has drawbacks. Paralytic or sedative agents may obscure signs of neurological or metabloic disorders. Lowered muscle tone may impair venous return, and hence cardiac output. The effects of such drugs are particularly hard to predict in infants.

Hyperventilation (often used to suppress spontaneous breathing efforts) has drawbacks, too. The resultant alkalosis reduces cerebral blood flow. Blood levels of calcium and magnesium are altered. Airway resistance increases and pulmonary compliance decreases with hypocarbia.[3] Finally, there is evidence of a shift in the carbon dioxide response curve, which makes weaning more difficult.

All of these pit-falls can be avoided by using continuous-flow IMV.

Please request Form 3-MV.

CAMBRIDGE, MASSACHUSETTS 02140

Uncommon Endotracheal Tubes From The Most Commonly Known Name In Anesthesia

Now here's a disposable endo tube worthy of the OHIO name!

Uncuffed, or with anatomically designed cuffs for a gentle seal. Clear tubes, Murphy eye, radiopaque tips, depth markings. And a unique inflation and pilot balloon assembly.

OHIO now makes a wide range of sizes. Each tube, sterile packed, for one-patient use.

It's common knowledge that OHIO is the leader in anesthesia equipment. A dependable supplier of inhalation agents and medical gases.

Now, watch us move ahead in disposables. Endo tubes, an anesthesia breathing circuit, filters, masks, airways, suction valves, catheters, tubing . . . And more coming. With many distribution and delivery facilities to keep you supplied.

Write for Catalog # 2604. Or contact your OHIO representative about disposables. For the common good of you and your patients.

SEND FOR COMPLETE LITERATURE

ANECTINE®
(succinylcholine chloride)
For controlled muscle relaxation adjunctive to anesthesia:

FLO-PACK® for prolonged relaxation

- instant-mix sterile powder interfaces with all major parenteral systems (vacuum or nonvacuum)
- each unit complete—no needle or syringe needed
- retains potency indefinitely
- no refrigeration required
- unbreakable, sterile plastic injection units of 500 and 1,000 mg

INJECTION for short-term relaxation

- a product of choice for intubation and other short procedures
- unique square bottle and bright yellow label for positive identification
- ready for immediate use
- 20 mg per cc . . . in 10 cc multidose vials
- flip-top cap for easy opening
- single or multiple use

ANECTINE®
(succinylcholine chloride)
THE LONG AND SHORT of surgical muscle relaxation

THIS DRUG SHOULD BE USED ONLY BY INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS AND HAZARDS.

DESCRIPTION: Anectine brand Succinylcholine Chloride is an ultra short-acting depolarizing type muscle relaxant. Chemically it is a di-quaternary base consisting of the di-chloride salt of the di-choline ester of succinic acid. It is a white, odorless, slightly bitter powder and very soluble in water. The drug is unstable with alkaline solutions, but relatively stable in acid solutions depending upon the concentration of the solution and the storage temperature. While solutions of succinylcholine chloride are sterilized by autoclaving, they should, nevertheless, be stored under refrigeration to preserve their potency.

INDICATIONS: Succinylcholine chloride is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may be employed to reduce the intensity of muscle contractions of pharmacologically or electrically induced convulsions.

CONTRAINDICATIONS: Succinylcholine is contraindicated for persons with a known hypersensitivity to the drug.

WARNINGS:

WARNING: SUCCINYLCHOLINE SHOULD BE USED ONLY BY THOSE SKILLED IN THE MANAGEMENT OF ARTIFICIAL RESPIRATION AND ONLY WHEN FACILITIES ARE INSTANTLY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND FOR PROVIDING ADEQUATE VENTILATION OF THE PATIENT, INCLUDING THE ADMINISTRATION OF OXYGEN UNDER POSITIVE PRESSURE AND THE ELIMINATION OF CARBON DIOXIDE., THE CLINICIAN MUST BE PREPARED TO ASSIST OR TO CONTROL RESPIRATION.

Succinylcholine should not be mixed with short-acting barbiturates in the same syringe, or administered simultaneously during intravenous infusion through the same needle. Solutions of succinylcholine have an acid pH whereas those of barbiturates are alkaline in reaction. Depending upon the resultant pH of a mixture of solutions of these drugs, either free barbituric acid may be precipitated or succinylcholine hydrolyzed.

Usage in Pregnancy The safe use of succinylcholine has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards.

PRECAUTIONS: Low levels of, or abnormal variants of plasma cholinesterase may be associated with prolonged respiratory depression or apnea following the use of succinylcholine. Low levels of plasma cholinesterase may occur in patients with severe liver disease or cirrhosis, severe anemia, malnutrition, severe dehydration, changes in body temperature, exposure to neurotoxic insecticides or those receiving antimalarial drugs. Succinylcholine should be administered with extreme care to such patients and dosage should be minimal. If low plasma cholinesterase activity is suspected, a small test dose of from 5 to 10 mg of succinylcholine may be administered, or relaxation may be produced by the cautious administration of a 0.1% solution of the drug by intravenous drip. Drugs which either inhibit plasma cholinesterase, such as neostigmine or phospholine iodide, or compete with succinylcholine for the enzyme, as does intravenous procaine, should not be given concurrently with succinylcholine.

Succinylcholine should be administered with great caution to patients with severe burns, those recovering from severe trauma, those suffering from electrolyte imbalance, those receiving quinidine, those who have been digitalized recently or who may have digitalis toxicity as serious cardiac arrhythmias or cardiac arrest may result. Great caution should be observed also in patients with pre-existing hyperkalemia or who are paraplegic, have suffered spinal neuraxis injury, or have degenerative or dystrophic neuromuscular disease, as such patients tend to become severely hyperkalemic when succinylcholine is given.

When succinylcholine is given over a prolonged period of time, the characteristic depolarization block of the myoneural junction may change to a non-depolarizing block which results in prolonged respiratory depression or apnea. Under such circumstances, small repeated doses of neostigmine may possibly act as an antagonist. A peripheral nerve stimulator (e.g., the Wellcome Peripheral Nerve Stimulator) may be used to ascertain the type of neuromuscular blockade. If a depolarization block is present both fast (tetanic) and slow (twitch) rates of nerve stimulation are well sustained, and post-tetanic facilitation is absent. If a non-depolarizing block is present there is post-tetanic facilitation and "fade" of successive stimuli on both fast (tetanic) and slow (twitch) rates of nerve stimulation.

Succinylcholine should be used with caution during ocular surgery and in patients with glaucoma. The drug should be employed with caution in patients with fractures or muscle spasm as the muscle fasciculations may cause additional trauma. Muscle fasciculations and hyperkalemia may be reduced by administering a small dose of a non-depolarizing relaxant. If other relaxants are to be used during the same procedure, the possibility of a synergistic or antagonistic effect should be considered.

During the past few years, reports have called attention to a fulminant syndrome, malignant hyperthermia, observed during anesthesia. Its etiology is not fully understood. Malignant hyperthermia occurs in genetically prone individuals of all ages and both sexes receiving potent anesthetics such as halothane, methoxyfluorothane, cyclopropane and diethyl ether. It appears to develop irrespective of the concomitant use of a muscle relaxant, but may be triggered by succinylcholine. Because of the seriousness of this syndrome and the need for early effective treatment of the patient, it is suggested that the continuous monitoring of the temperature will serve as an aid to the early recognition of malignant hyperthermia.

ADVERSE REACTIONS: Adverse reactions consist primarily of an extension of the drug's pharmacological actions. Profound and prolonged muscle relaxation may occur, resulting in respiratory depression to the point of apnea. Hypersensitivity to the drug may exist in rare instances.

The following adverse reactions have been reported: bradycardia, tachycardia, hypertension, hypotension, arrhythmias, cardiac arrest, prolonged respiratory depression or apnea, hyperthermia, increased intraocular pressure, muscle fasciculation, postoperative muscle pain, myoglobinemia and excessive salivation.

MANAGEMENT OF ADVERSE REACTIONS: Apnea or prolonged muscle paralysis should be treated with controlled respiration.

The use of neostigmine to reverse a non-depolarization block is a medical decision which must be made upon the basis of the individual clinical pharmacology and the experience and judgment of the clinician. When neostigmine is used atropine should also be administered.

SUPPLIED: Injection, Multi-dose vials, 20 mg cc, 10 cc, boxes of 12 vials. Flo-Pack® Sterile Powder 500 mg and 1,000 mg, boxes of 12.

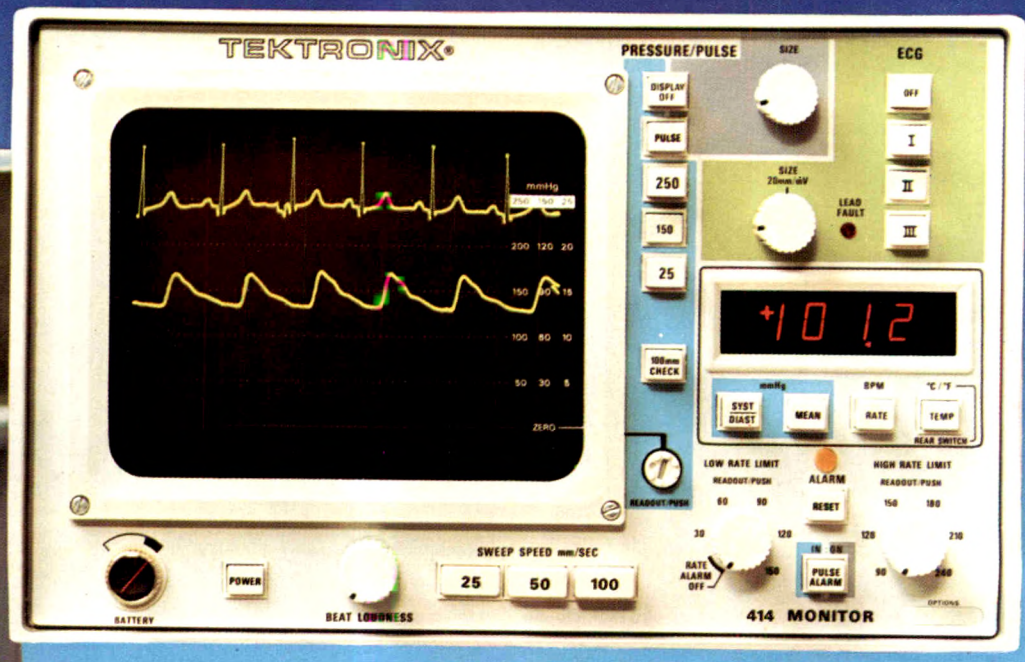
Introducing the most complete monitor capability in a single compact instrument.



NEW Tektronix 414 Portable Patient Monitor

ECG. Temperature. Arterial, venous or pulmonary wedge pressure. Peripheral pulse. Only Tektronix 414 offers every feature for monitoring these vital signs—all neatly packaged in a single, portable unit. For increased accuracy and convenience, the 414 gives digital readout of heart rate, systolic/diastolic blood pressures, mean blood pressure, or temperature. Rate alarm limits are also set digitally.

And because the 414 permits cordless (battery) operation, it can be as easily used for cardiac catheterization as for surgery and recovery. Weight of a fully equipped 414 is approximately 12 lbs.

For more information or a demonstration of any of Tektronix Portable Patient Monitors in your facility, please write to Tektronix, Inc., P.O. Box 500, Beaverton, Oregon 97077. *Or call collect:* (503) 644-0161, extension 6510.

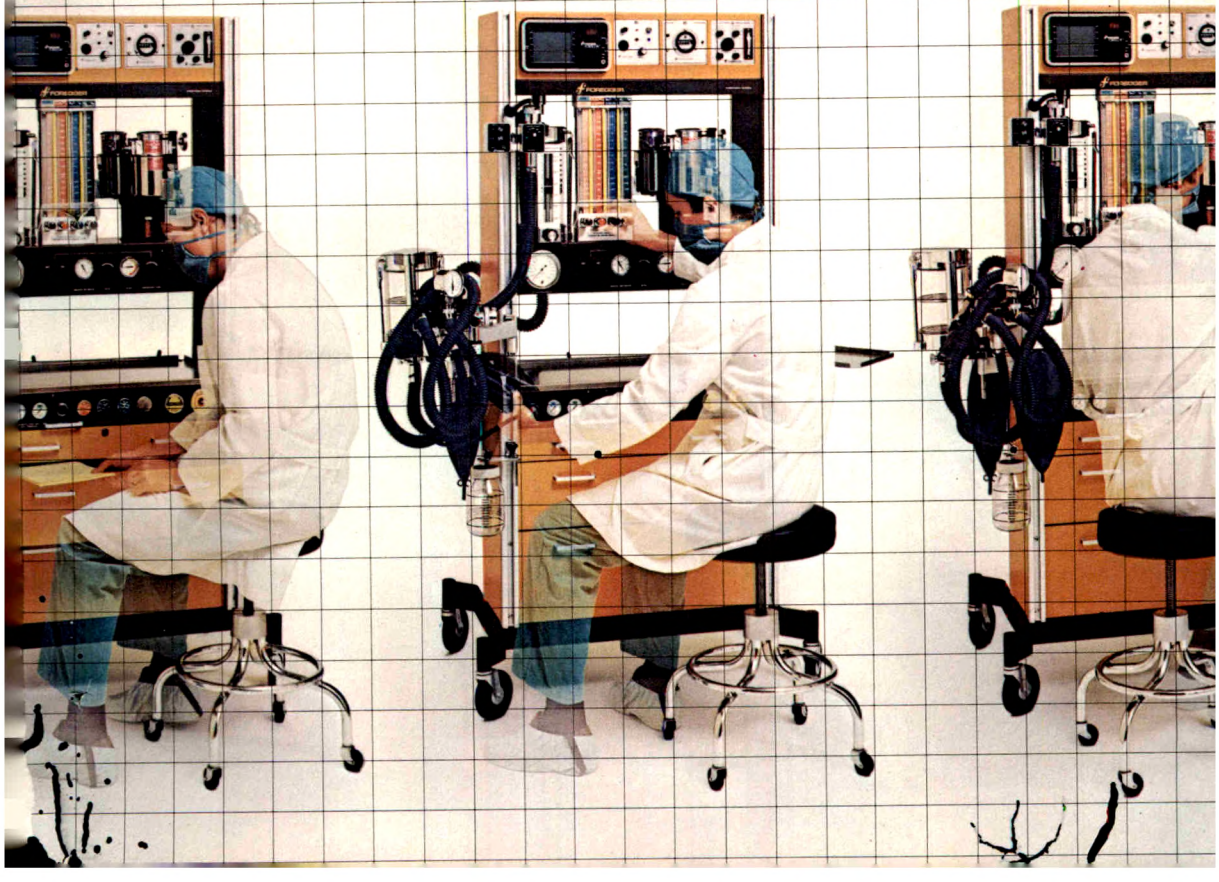
Excellence in Patient Monitoring

TEKTRONIX®
committed to technical excellence

P24572

Introducing The Human-Engineered Anesthesia Control Center.

The FOREGGER® 710



The FOREGGER 710 Anesthesia Control Center. Unlike Anything You've Ever Seen.

Think of what it is like using a typical anesthesia machine. Now, look at the new FOREGGER 710 Anesthesia Control Center. Notice the completeness, compactness, accessibility and visibility of the components. Everything is in one place, within reach . . . without dangling wires and add-on components. That's why we call it the FOREGGER 710 Anesthesia Control Center.

Unlike existing anesthesia machines, the FOREGGER 710 Anesthesia Control Center is human engineered. The design revolves around you. All of the controls for both fixed and movable components are operated from a comfortable, working position. And this ease of control is complemented by the latest innovations in anesthesia equipment design.

Take, for instance, the unique rotating Vaporizer Turret. It accommodates up to three vaporizers, including the Foregger Copper Kettle® Vaporizer and Foregger Direct Reading Vaporizers. When the Turret is locked into place, there is no doubt which vaporizer is in circuit. Possible contamination from anesthetic agents contained in the other vaporizers is eliminated.

Then there are the Direct Reading Vaporizers designed for the administration of a specific liquid anesthetic, over a wide range of temperatures and flow rates. The Copper Kettle Vaporizer, on the other hand, affords you constant and precise control in both increments and decrements, while providing simple and accurate administration of an anesthetic agent.

There's also a built-in Anesthesia Ventilator that features fluidic circuitry, independent controls, and a mode selector switch that enables you to transfer from ventilator to bag without changing tubes or adjusting the pressure relief valve. It gives you the convenience of easy readouts and the efficiency of direct control. And it's easy to clean.

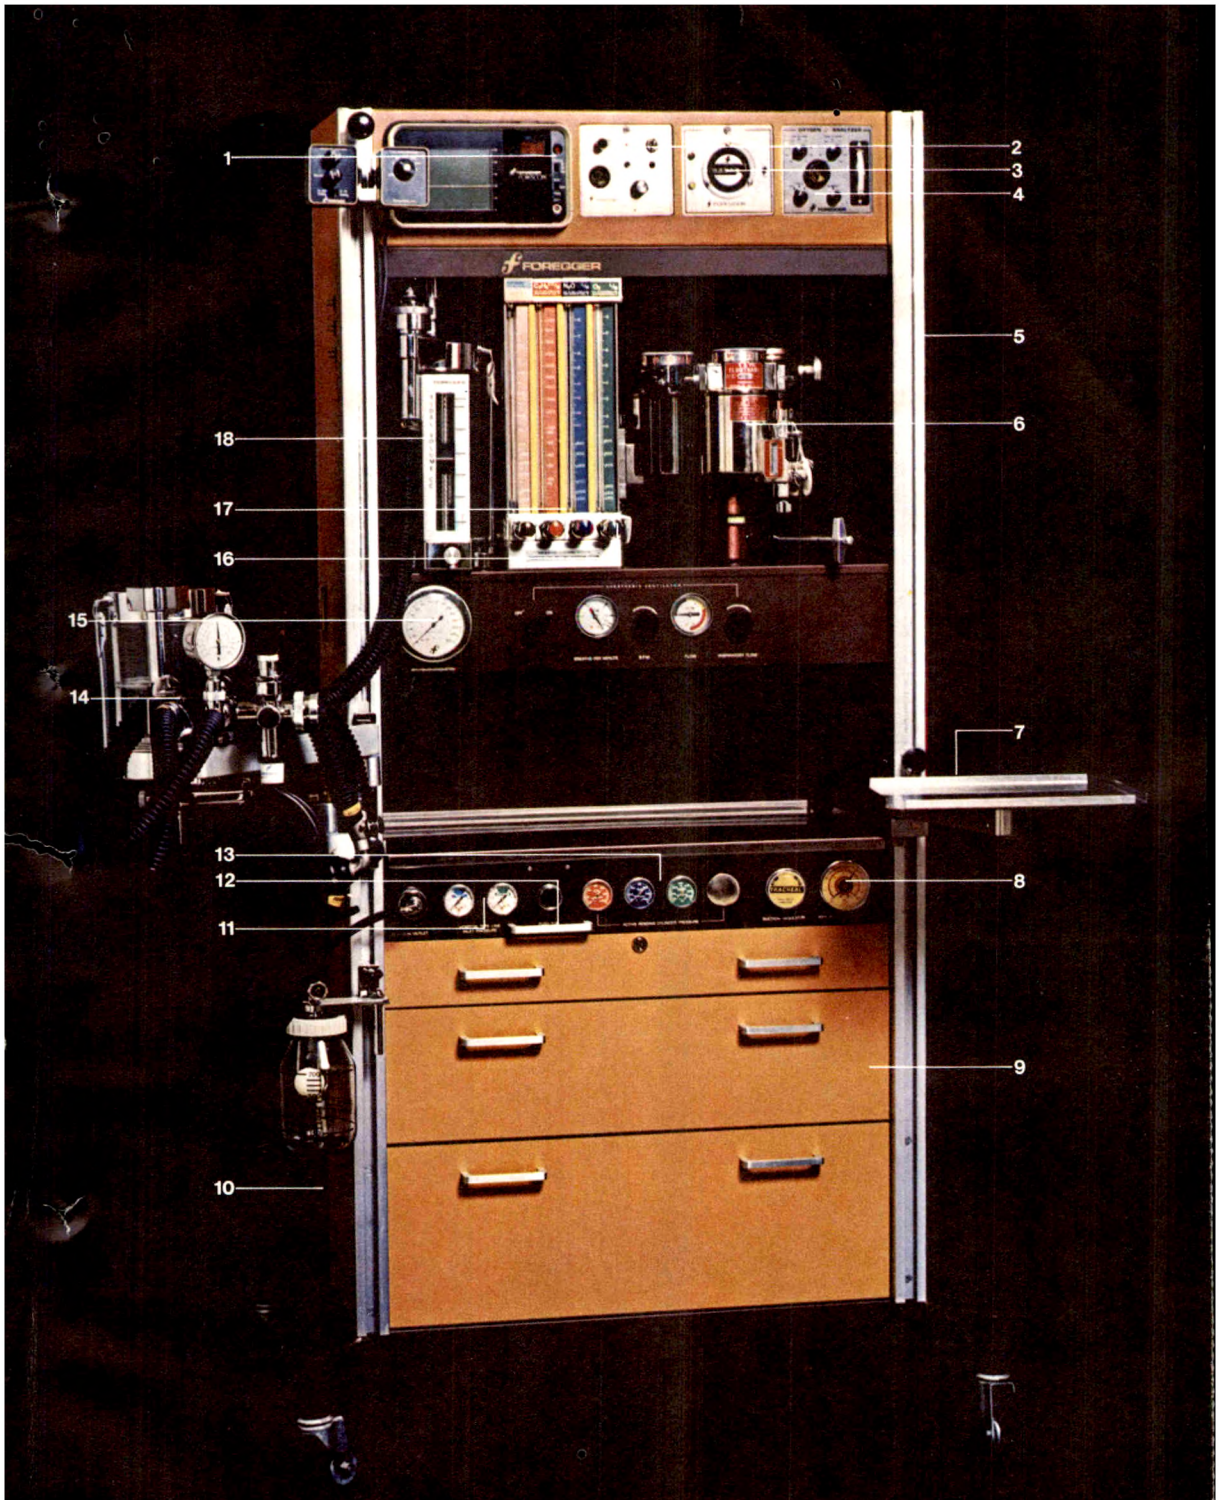
Storage is human-engineered too! Cabinetry in the new FOREGGER 710 Anesthesia Control Center combines linear designed storage with easy accessibility and large capacity.

The Monitoring System, which provides a wide range of physiological monitoring capability, is located where you need it during procedures. Easy to see and reach, it includes a physiological monitor (ECG, EEG, temperature, pulse rate, and pressure), an Oxygen Analyzer, Ventilator Disconnect Alarm, and an Elapsed Timer.

In addition, the FOREGGER 710 Anesthesia Control Center has a built-in Oxygen Start, which automatically shuts off all other gases when the oxygen flow is reduced to a predetermined level. Plus, four parallel accessory tracks to mount and adjust FOREGGER 710 Anesthesia Control Center accessories. All of which add another dimension to overall flexibility.

And that's where you should place the new FOREGGER 710 Anesthesia Control Center. Over all. In capabilities. Flexibilities. And human engineering. Take a look at its other unlike features and we think you'll agree . . . The FOREGGER 710 Anesthesia Control Center is unlike anything you have seen before. For more information about what human engineering with everything in one place can mean to you, fill out and return the attached card.

With FOREGGER—It's The Unlikely Things About Us That You'll Like.



1. Physiological Monitor

PEOPLE AND PLACES

"Anesthesia and the Respiratory System" is the title of the Fourth Annual Anesthesiology Review Course to be held February 28-29, 1976, by the Department of Anesthesiology and the Division of Continuing Medical Education of the University of Alabama in Birmingham with the co-sponsorship of the Alabama State Society of Anesthesiologists.

This Review Course is designed to survey concepts in the management of respiratory problems likely to be encountered in anesthetic practice. The program is clinically oriented in its entirety.

On Friday, February 27, and Monday, March 1, 1976, arrangements have been made for participants in the Review Course to observe anesthetic procedures, respirator demonstrations, nerve blocks, etc., at the UAB Medical Center. There will also be an opportunity for group discussions.

For more information, write to: Review Course, c/o Department of Anesthesiology, University of Alabama Medical Center, University Station, Birmingham, Alabama 35294.

* * *

The First Annual Vail Conference in Respiratory Therapy sponsored by the Department of Anesthesiology, University of Miami, Miami, Florida, will be held at the Lion Square Lodge in Vail, Colorado, February 28 - March 6, 1976.

* * *

The Obstetric Anaesthetists' Association in the United Kingdom will hold their next meeting in the University of Nottingham on March 26, 1976. **Dr. B. A. Waldron,** Consultant Anaesthetist, Nottingham City Hospital, Hucknall Road, Nottingham, will be the host for this meeting.

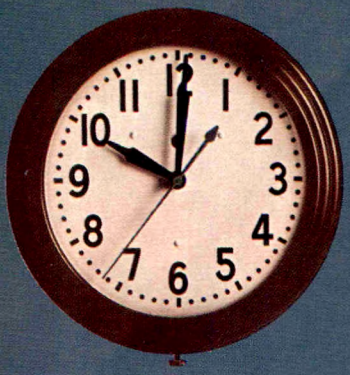
Their following meeting will be on September 24, 1976, in the University of South Manchester. All people wishing to present a paper at the Manchester meeting should write to **Dr. Valerie Hey,** Withington Hospital, West Didsbury, Manchester, before May 1, 1976.

* * *

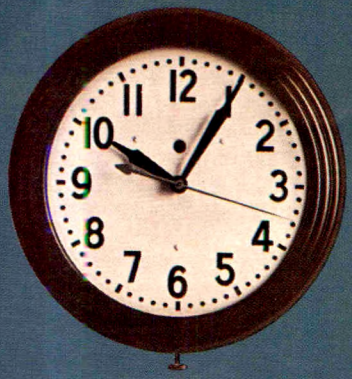
The Connecticut State Society of Anesthesiologists will present the 9th Biennial Connecticut Postgraduate Seminar in Anesthesiology at the Hunt Memorial Auditorium of the Hartford Medical Society Building, 230 Scarborough Street in Hartford, Connecticut, on Friday, May 7, and Saturday, May 8, 1976. The subject is "Clinical Problems in Anesthesia." Details may be obtained from **James C. Rouman, MD,** Chairman, Postgraduate Education Committee, 85 Jefferson Street, Suite 407, Hartford, Connecticut 06106.

* * *

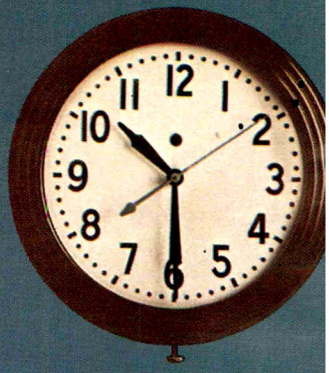
Dr. M. Digby Leigh, a long-time friend of many of us, died September 5, 1975, in Palm Springs, California. Doctor Leigh was certified in Anaesthesia by the Royal College of Physicians, Canada, and by the American Board of Anesthesiology. He was the chief author of two editions of *Pediatric Anesthesiology,* 1948 and 1960, and of numerous articles. He devised several pieces of anesthetic equipment, most notably the non-rebreathing valve and the infant circle filter. His students and associates knew him as a superb teacher and shrewd clinician, as well as an inspiring and demanding, but very much respected and admired "Chief."



SUBLIMAZE® (fentanyl) has a uniquely short duration of analgesic action—for more precise control and minimal risk of prolonged narcotic effects.

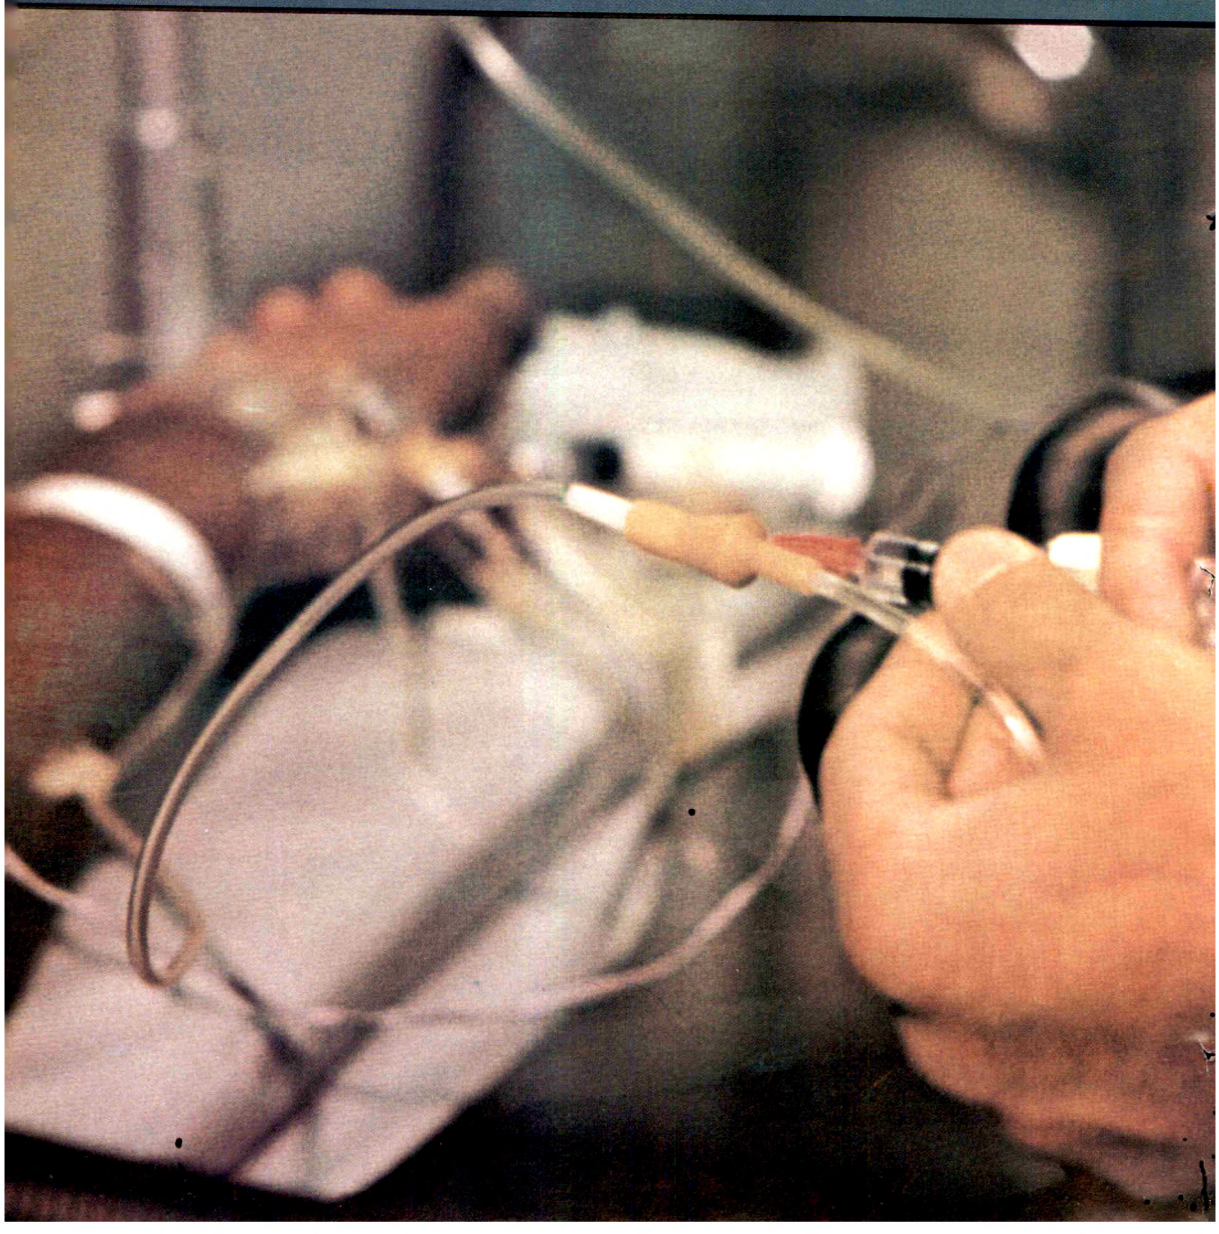


Within 5 minutes I.V., SUBLIMAZE® (fentanyl) reaches its peak analgesic effect.



Within 30 to 60 minutes I.V., the analgesic effect of SUBLIMAZE® (fentanyl) is almost completely dissipated.†

† Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.



For potent narcotic analgesic action with rapid onset and short duration:

SUBLIMAZE fentanyl provides profound analgesia without hypnosis and with little or no sedation. With this analgesia as a foundation, it is possible to use light general anesthesia in most cases.

SUBLIMAZE fentanyl is particularly suited for maintenance of analgesia after INNOVAR® injection* has been used for induction. It may also be used preoperatively, during surgery with any common general or regional anesthetic agent, and in the immediate postoperative period whenever the need for potent analgesic action arises.

SUBLIMAZE fentanyl is available both alone and as a component of INNOVAR injection.*

*INNOVAR injection is composed of a 50:1 mixture of droperidol 2.5 mg./cc. and fentanyl 0.05 mg./cc., with lactic acid for adjustment of pH to 3.5 ± 0.3.

SUBLIMAZE® (fentanyl) offers:

☐ Almost immediate analgesia—peak effect within 5 minutes I.V., 8 minutes I.M.

☐ Short duration of analgesic action—30 to 60 minutes with a single I.V. dose of up to 0.1 mg. (Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.)

☐ No evidence of liver, heart, or kidney toxicity—expecially valuable in poor-risk patients. However, the drug should be administered cautiously in the presence of liver or kidney dysfunction or cardiac arrhythmias, and the dose should be appropriately reduced in poor-risk patients.

☐ Immediate reversibility by narcotic antagonists.

☐ Little or no histamine release—decreasing the risk of cardiovascular instability.

☐ Minimal emetic effect—has been used successfully to prepare nonfasting patients for awake intubation.

☐ Prevention or reversal of emergence delirium and tachypnea.

SUBLIMAZE® Ⓒ Ⅱ (fentanyl) injection

0.05 mg./cc. as the citrate.
Warning: May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0—7.5

INNOVAR® injection and SUBLIMAZE® (fentanyl) injection are available for use only upon direction of a physician. For information relating to Contraindications, Warnings, Precautions and Adverse Reactions for SUBLIMAZE fentanyl, please turn page.

© McNeil Laboratories, Inc., 1974

SUBLIMAZE® (fentanyl) injection

Description
Each cc. contains:
Fentanyl as the citrate . . . . . 0.05 mg.
Warning—May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0–7.5
FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY.

Actions SUBLIMAZE fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. SUBLIMAZE fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. SUBLIMAZE fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays and skin wheal testing in man, as well as *in vivo* testing in dogs, indicate that histamine release rarely occurs with SUBLIMAZE fentanyl.

SUBLIMAZE fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of SUBLIMAZE fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours.

Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics it may be considerably longer than the analgesic effect.

Indications SUBLIMAZE fentanyl is indicated:
—for analgesic action of short duration during the anesthetic periods, premedication, induction, and maintenance, and in the immediate postoperative period (recovery room) as the need arises.
—for use as a narcotic analgesic supplement in general or regional anesthesia.
—for administration with a neuroleptic such as INAPSINE® (droperidol) injection as an anesthetic premedication, for the induction of anesthesia and as an adjunct in the maintenance of general and regional anesthesia.

Contraindications SUBLIMAZE fentanyl is contraindicated in patients who are hypersensitive to the drug.

Warnings PATIENTS WHO HAVE RECEIVED *SUBLIMAZE* FENTANYL SHOULD HAVE APPROPRIATE SURVEILLANCE, RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

If SUBLIMAZE fentanyl is administered with a tranquilizer such as INAPSINE droperidol, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action. In addition, when such a combination is used *fluids and other countermeasures to manage hypotension should be available.*

As with other potent narcotics, the respiratory depressant effect of SUBLIMAZE fentanyl persists longer than the measured analgesic effect. The total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, should be used in reduced doses initially, as low as 1/4 to 1/3 those usually recommended. A neuromuscular blocking agent compatible with the patient's condition may be required to control muscle rigidity which may develop with the use of SUBLIMAZE fentanyl.

Drug Dependence: SUBLIMAZE fentanyl can produce drug dependence of the morphine type and therefore has the potential for being abused.

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl in this regard has not been established, the use of SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: SUBLIMAZE fentanyl should be used with caution in patients who may be particularly susceptible to respiratory depression, such as comatose patients who may have a head injury or brain tumor. In addition, SUBLIMAZE fentanyl may obscure the clinical course of patients with head injury.

Usage in Children: The safety of SUBLIMAZE fentanyl in children younger than two years of age has not been established.

Usage in Pregnancy: The safe use of SUBLIMAZE fentanyl has not been established with respect to possible adverse effects upon fetal development. Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

Precautions *The initial dose of SUBLIMAZE fentanyl should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves. Through other mechanisms (see Actions) SUBLIMAZE fentanyl can also alter respiration. When SUBLIMAZE fentanyl is used to supplement these forms of anesthesia, the anesthetist should be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for these forms of anesthesia. When used with a tranquilizer such as INAPSINE droperidol, blood pressure may be altered and hypotension can occur.

Vital signs should be monitored routinely.

SUBLIMAZE fentanyl should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised respiration. In such patients, narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration. Postoperatively, respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone; consult individual prescribing information before using). Should respiration be compromised by muscle rigidity, assisted or controlled respiration and possibly a neuromuscular blocking agent will be required. The occurrence of muscle rigidity is related to the speed of intravenous injection and the incidence can be reduced by slow intravenous injection.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, pulmonary arterial pressure may be decreased. This fact should be considered by those who conduct diagnostic and surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) will have additive or potentiating effects with SUBLIMAZE fentanyl. When patients have received such drugs, the dose of SUBLIMAZE fentanyl required will be less than usual. Likewise, following administration of SUBLIMAZE fentanyl the dose of other CNS depressant drugs should be reduced.

SUBLIMAZE fentanyl should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

SUBLIMAZE fentanyl may produce bradycardia, which may be treated with atropine; however, SUBLIMAZE fentanyl should be used with caution in patients with cardiac bradyarrhythmias.

When SUBLIMAZE fentanyl is used with a tranquilizer such as INAPSINE droperidol, hypotension can occur. If this occurs the possibility of hypovolemia should also be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. Care should be exercised in moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus other countermeasures do not correct hypotension, the administration of pressor agents other than epinephrine should be considered. Because of the alpha-adrenergic blocking action of INAPSINE droperidol, epinephrine may paradoxically decrease the blood pressure in patients treated with INAPSINE droperidol.

Adverse Reactions As with other narcotic analgesics, the most common serious adverse reactions reported to occur with SUBLIMAZE fentanyl are respiratory depression, apnea, muscular rigidity, and bradycardia; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Other adverse reactions that have been reported are hypotension, dizziness, blurred vision, nausea, emesis, laryngospasm, and diaphoresis.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, the following adverse reactions can occur: chills and/or shivering, restlessness, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression); extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with antiparkinson agents. Postoperative drowsiness is also frequently reported following the use of INAPSINE droperidol.

Overdosage ***Manifestations:*** The manifestations of SUBLIMAZE fentanyl overdosage are an extension of its pharmacologic actions.
Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. A specific narcotic antagonist such as nalorphine, levallorphan, or naloxone should be available for use as indicated to manage respiratory depression. This does not preclude the use of more immediate countermeasures. Consult the package insert for the individual narcotic antagonists for details about use.

How Supplied SUBLIMAZE® (fentanyl) injection is supplied in 2 cc. (**NDC** 0045-0180-03) and 5 cc. (**NDC** 0045-0180-05) ampuls, in packages of 12.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

U.S. Patent No. 3,164,600

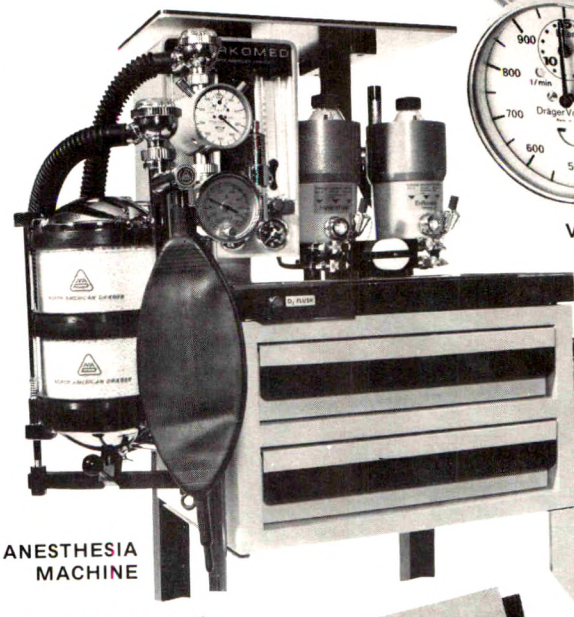
McNEIL McNeil Laboratories, Inc.
Fort Washington, Pa. 19034

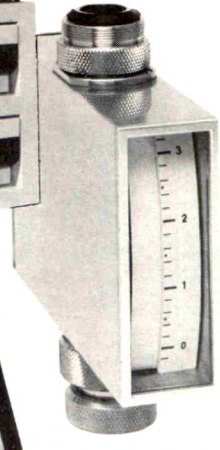
All Drager

VAPORIZER



ANESTHESIA MACHINE

VOLUMETER



ANESTHESIA ANALYZER

VAPOR VAPORIZER — Outstanding accuracy at flow rates ranging from 0.3 l/min. to 12 l/min. Back pressure compensated. Available for Halothane, Enflurane, Methoxyflurane & Ether.

NARKOTEST-M ANESTHESIA ANALYZER — Fits all current anesthesia absorbers or can be mounted on a portable stand. Provides in-line continuous reading of inspired Halothane concentrations. The NARKOTEST can also be used to measure expiratory values of various anesthetic agents.

MINUTE VOLUMETER 2000 — Measures both minute volume and tidal volume. A built-in timer will actuate the measuring mechanism for one minute and store the result until cancelled, or the unit can be used to continuously measure tidal volumes. Moisture or the composition of measured gas will not affect the unit. It can be mounted on most anesthesia absorbers and ventilators, or used portably.

NARKOMED ANESTHESIA MACHINE — A refreshing new dimension in anesthesia design and styling — NARKOMED — a modular anesthesia breathing system designed to include the widest variety of options.

ANTILIRIUM
(Physostigmine Salicylate)

REVERSES MOST POST-OPERATIVE DELIRIUM AND PROLONGED SOMNOLENCE

Before prescribing, please consult complete product information, a summary of which follows:

ACTION: ANTILIRIUM (physostigmine salicylate) is a salicylic acid derivative of an alkaloid extracted from seeds of Physostigma Venenosum (calabar bean). The action of the parasympathetic nerves is intermediated by the formation of acetylcholine at the peripheral end of these nerves. Physostigmine inhibits the destructive action of cholinesterase and thereby prolongs and exaggerates the effect of the acetylcholine.

Physostigmine contains a tertiary amine and easily crosses the blood brain barrier, while neostigmine contains a quaternary amine and is not capable of crossing the structure. This may explain why neostigmine does not cause reversal of anticholinergic-induced delirium while physostigmine does.

INDICATIONS: TO REVERSE THE TOXIC EFFECTS UPON THE CENTRAL NERVOUS SYSTEM CAUSED BY DRUGS IN CLINICAL OR TOXIC DOSAGES CAPABLE OF PRODUCING ANTICHOLINERGIC POISONING.

SEVERE ANTICHOLINERGIC POISONING MAY PRODUCE: COMA, MEDULLARY PARALYSIS AND DEATH.

CENTRAL TOXIC EFFECTS MAY INCLUDE: HALLUCINATIONS, DELIRIUM, DISORIENTATION, ANXIETY AND HYPERACTIVITY.

Dramatic reversal within minutes of coma, hallucinations, and other signs can be expected if the diagnosis is correct and the patient has not suffered anoxia or other insult. Therapeutic doses may be necessary at intervals as life-threatening signs recur. Physostigmine is destroyed in the body in 60 to 120 minutes.

CONTRAINDICATIONS: Physostigmine should not be used in the presence of asthma, gangrene, diabetes, cardiovascular disease, mechanical obstruction of the intestines or urogenital tract or any vagotonic state, and in patients receiving choline esters or depolarizing neuromuscular blocking agents.

WARNING: If excessive symptoms of salivation, emesis, urination and defecation occur, the use of ANTILIRIUM should be terminated. If excessive sweating or nausea occur, the dosage should be reduced.

Intravenous administration should be at a slow, controlled rate, no more than 1 mg. per minute (see dosage). Rapid administration can cause bradycardia, hypersalivation leading to respiratory difficulties and possibly convulsions.

An overdosage of ANTILIRIUM can cause a cholinergic crisis.

PRECAUTIONS: Because of the possibility of hypersensitivity in an occasional patient, atropine sulfate injection should always be at hand since it is an antagonist and antidote for physostigmine.

ADMINISTRATION AND DOSAGE: The usual adult dose of ANTILIRIUM is 0.5 to 2.0 mg. intramuscularly or intravenously. Intravenous administration should be at a slow, controlled rate of no more than 1 mg. per minute. It may be necessary to repeat dosages of 1 mg. to 4 mg. at intervals as life threatening signs such as arrhythmias, convulsions and deep coma recur.

IN ALL CASES OF POISONING, THE USUAL SUPPORTIVE MEASURES SHOULD BE UNDERTAKEN.

SUPPLIED: 2 ml. ampules containing: PHYSOSTIGMINE SALICYLATE 1 mg. per ml. Packed 12 ampules per box.

NDC 0456-1037-12

CAUTION: Federal law prohibits dispensing without prescription.

Talwin®
Brand of pentazocine (as lactate)
Analgesic for Parenteral Use

Ampuls: 30 mg. (1 ml.), **45 mg.** (1½ ml.), and **60 mg.** (2 ml.)
Vials: (10 ml.) 30 mg./ml.
30 mg. for I.V., I.M., or S.C. use
45 mg. for I.M. or S.C. use
60 mg. for I.M. or S.C. use

Indications: For the relief of moderate to severe pain. Talwin may also be used for preoperative or preanesthetic medication and as a supplement to surgical anesthesia.

Contraindication: Talwin should not be administered to patients who are hypersensitive to it.

Warnings: *Drug Dependence. Special care should be exercised in prescribing pentazocine for emotionally unstable patients and for those with a history of drug misuse. Such patients should be closely supervised when long-term therapy is contemplated. There have been instances of psychological and physical dependence on Talwin in patients with such a history and, rarely, in patients without such a history. Abrupt discontinuance following the extended use of parenteral Talwin has resulted in symptoms such as abdominal cramps, elevated temperature, rhinorrhea, restlessness, anxiety, and lacrimation. Even when these occurred, discontinuance has been accomplished with minimal difficulty. In the rare patient in whom more than minor difficulty has been encountered, reinstitution of parenteral Talwin with gradual withdrawal has ameliorated the patient's symptoms. Substituting methadone or other narcotics for Talwin in the treatment of the Talwin abstinence syndrome should be avoided.*

In prescribing parenteral Talwin for chronic use, particularly if the drug is to be self-administered, the physician should take precautions to avoid increases in dose and frequency of injection by the patient and to prevent the use of the drug in anticipation of pain rather than for the relief of pain.

Just as with all medication, the oral form of Talwin is preferable for chronic administration.

Head Injury and Increased Intracranial Pressure. The respiratory depressant effects of Talwin and its potential for elevating cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions, or a preexisting increase in intracranial pressure. Furthermore, Talwin can produce effects which may obscure the clinical course of patients with head injuries. In such patients, Talwin must be used with extreme caution and only if its use is deemed essential.

Usage in Pregnancy. Safe use of Talwin during pregnancy (other than labor) has not been established. Animal reproduction studies have not demonstrated teratogenic or embryotoxic effects. However, Talwin should be administered to pregnant patients (other than labor) only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. Patients receiving Talwin during labor have experienced no adverse effects other than those that occur with commonly used analgesics. Talwin should be used with caution in women delivering premature infants.

Acute CNS Manifestations. Patients receiving therapeutic doses of Talwin have experienced, in rare instances, hallucinations (usually visual), disorientation, and confusion which have cleared spontaneously within a period of hours. The mechanism of this reaction is not known. Such patients should be very closely observed and vital signs checked. If the drug is reinstituted it should be done with caution since the acute CNS manifestations may recur.

Usage in Children. Because clinical experience in children under twelve years of age is limited, the use of Talwin in this age group is not recommended.

Ambulatory Patients. Since sedation, dizziness, and occasional euphoria have been noted, ambulatory patients should be warned not to operate machinery, drive cars, or unnecessarily expose themselves to hazards.

Precautions: *Certain Respiratory Conditions.* The possibility that Talwin may cause respiratory depression should be considered in treatment of patients with bronchial asthma. Talwin should be administered only with caution and in low dosage to patients with respiratory depression (e.g., from other medication, uremia, or severe infection), severely limited respiratory reserve, obstructive respiratory conditions, or cyanosis.

Impaired Renal or Hepatic Function. Although laboratory tests have not indicated that Talwin causes or increases renal or hepatic impairment, the drug should be administered with caution to patients with such impairment. Extensive liver disease appears to predispose to greater side effects (e.g., marked apprehension, anxiety, dizziness, sleepiness) from the usual clinical dose, and may be the result of decreased metabolism of the drug by the liver.

Myocardial Infarction. As with all drugs, Talwin should be used with caution in patients with myocardial infarction who have nausea or vomiting.

Biliary Surgery. As with all strong analgesics, Talwin should be used with caution in patients about to undergo surgery of the biliary tract since it may cause spasm of the sphincter of Oddi.

Patients Receiving Narcotics. Talwin is a mild narcotic antagonist. Some patients previously given narcotics, including methadone for the daily treatment of narcotic dependence, have experienced withdrawal symptoms after receiving Talwin.

CNS Effect. Caution should be used when Talwin is administered to patients prone to seizures; seizures have occurred in a few such patients in association with the use of Talwin although no cause and effect relationship has been established.

Tissue Damage at Injection Sites. Severe sclerosis of the skin, subcutaneous tissues, and underlying muscle have occurred at the injection sites of patients who have received multiple doses of pentazocine, as lactate. Constant rotation of injection sites is, therefore, recommended. In addition, animal studies have suggested that Talwin may be tolerated less well subcutaneously than intramuscularly.

Adverse Reactions: The most commonly occurring reactions are: nausea, dizziness or lightheadedness, vomiting, euphoria.

Dermatologic Reactions: Soft tissue induration, nodules, and cutaneous depression can occur at injection sites. Ulceration (sloughing) and severe sclerosis of the skin and subcutaneous tissues (and, rarely, underlying muscle) have been reported after multiple doses.

Infrequently occurring reactions are—*respiratory:* respiratory depression, dyspnea, transient apnea in a small number of newborn infants whose mothers received Talwin during labor; *cardiovascular:* circulatory depression, shock, hypertension; *CNS effects:* sedation, alteration of mood (nervousness, apprehension, depression, floating feeling), dreams; *gastrointestinal:* constipation, dry mouth; *dermatologic including local:* diaphoresis, sting on injection, flushed skin including plethora, dermatitis including pruritus; *other:* urinary retention, headache, paresthesia, alterations in rate or strength of uterine contractions during labor.

Rarely reported reactions include—*neuromuscular and psychiatric:* muscle tremor, insomnia, disorientation, hallucinations; *gastrointestinal:* taste alteration, diarrhea and cramps; *ophthalmic:* blurred vision, nystagmus, diplopia, miosis; *hematologic:* depression of white blood cells (especially granulocytes), which is usually reversible, moderate transient eosinophilia; *other:* tachycardia, weakness or faintness, chills, allergic reactions including angioedema, edema of the face, vascular purpura, toxic epidermal necrolysis.

See *Acute CNS Manifestations* and *Drug Dependence* under **WARNINGS.**

Dosage and Administration: *Adults, Excluding Patients in Labor.* The recommended single parenteral dose is 30 mg. by intramuscular, subcutaneous, or intravenous route. This may be repeated every 3 to 4 hours. Doses in excess of 30 mg. intravenously or 60 mg. intramuscularly or subcutaneously are not recommended. Total daily dosage should not exceed 360 mg. When frequent daily injections are needed over a prolonged period, intramuscular administration is preferable to subcutaneous. In addition, constant rotation of injection sites (e.g., the upper outer quadrants of the buttocks, mid-lateral aspects of the thighs, and the deltoid areas) is recommended.

Patients in Labor. A single, intramuscular 30 mg. dose has been most commonly administered. An intravenous 20 mg. dose has given adequate pain relief to some patients in labor when contractions become regular, and this dose may be given two or three times at two- to three-hour intervals, as needed.

Children Under 12 Years of Age. Since clinical experience in children under twelve years of age is limited, the use of Talwin in this age group is not recommended.

CAUTION. Talwin should not be mixed in the same syringe with soluble barbiturates because precipitation will occur.

Overdosage: *Manifestations:* Clinical experience with Talwin overdosage has been insufficient to define the signs of this condition. *Treatment:* Oxygen, intravenous fluids, vasopressors, and other supportive measures should be employed as indicated. Assisted or controlled ventilation should also be considered. Although nalorphine and levallorphan are *not* effective antidotes for respiratory depression due to overdosage or unusual sensitivity to Talwin, parenteral naloxone (Narcan®, available through Endo Laboratories) is a specific and effective antagonist.

Talwin is not subject to narcotic controls.

How Supplied: *Uni-Amp® — Individual unit dose ampuls of 1 ml. (30 mg.) and 2 ml. (60 mg.)* in boxes of 25.

Ampuls of 1 ml. (30 mg.) in (nested) boxes of 25.

Ampuls of 1½ ml. (45 mg.) in boxes of 10 and 100.

Ampuls of 2 ml. (60 mg.) in (nested) boxes of 25.

Each 1 ml. contains Talwin (brand of pentazocine) as lactate equivalent to 30 mg. base and 2.8 mg. sodium chloride, in water for injection.

Multiple dose vials of 10 ml., each 1 ml. containing Talwin (brand of pentazocine) as lactate equivalent to 30 mg. base, 2 mg. acetone sodium bisulfite, 1.5 mg. sodium chloride, and 1 mg. methylparaben as preservative, in water for injection. Boxes of 1. The pH of Talwin solution is adjusted between 4 and 5 with lactic acid and sodium hydroxide. The air in the ampuls and vials has been displaced by nitrogen gas.

Winthrop Laboratories, New York, N.Y. 10016

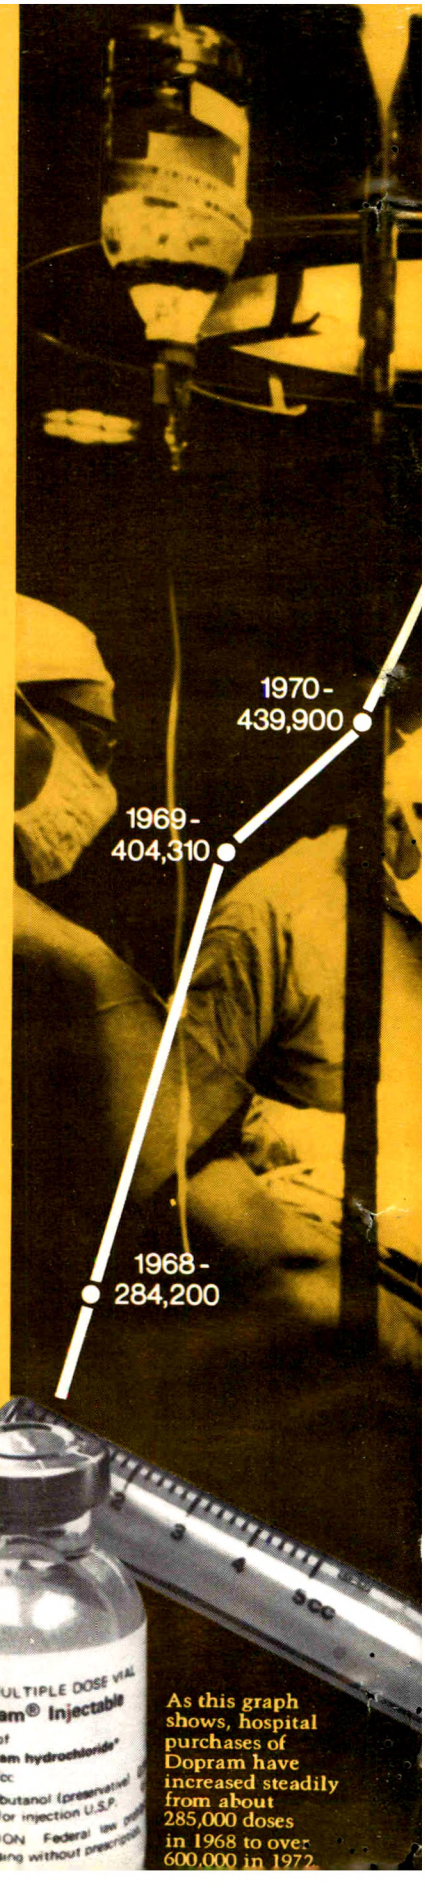
In all types of hospitals across the United States, its usage grows–

Dopram®
Injectable
(doxapram HCl)

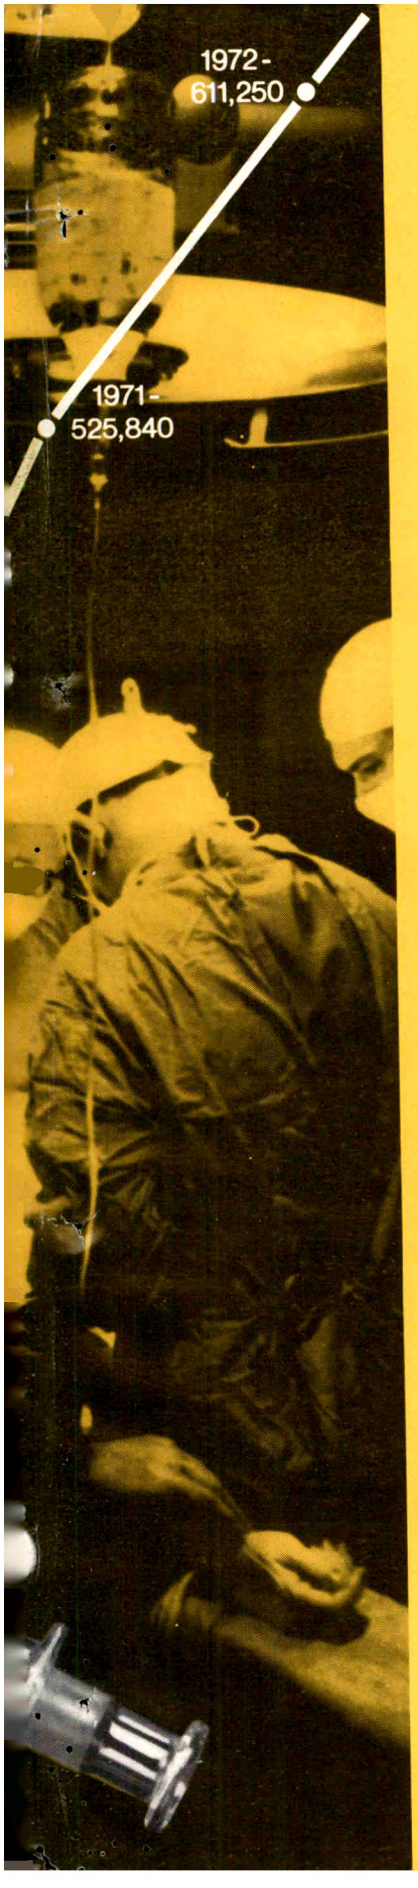
Seven years ago, A. H. Robins introduced Dopram, a unique respiratory stimulant developed in the company's research laboratories. What made this drug so useful to the anesthesiologist was its ability to rapidly restore the respiratory drive in patients with drug-induced post anesthetic depression.

Usage of Dopram has been steadily increasing each year, until today it has become a very important drug in the armamentarium of more than 1,500 hospitals of all types in all 50 states, the District of Columbia, and a number of foreign countries. These hospitals purchased more than 600,000 doses in 1972 alone.

Dopram–an important drug in anesthesiology. Try it for sighs!



As this graph shows, hospital purchases of Dopram have increased steadily from about 285,000 doses in 1968 to over 600,000 in 1972.



Indications

1. To stimulate respiration in patients with drug induced post-anesthetic respiratory depression or apnea other than that due to muscle relaxant drugs.
2. To pharmacologically stimulate deep breathing in the so-called "stir-up" regimen in the post-operative patient. Simultaneous administration of oxygen is desirable.
3. To hasten arousal and return of protective pharyngeal and laryngeal reflexes.
4. To aid in the differential diagnosis of post-anesthetic respiratory depression. Failure to adequately stimulate respiration suggests residual muscle relaxant effect.
5. To stimulate respiration, hasten arousal and to encourage the return of laryngopharyngeal reflexes in patients with mild to moderate respiratory and CNS depression due to drug overdosage.

Contraindications—Epilepsy and other convulsive states: incompetence of the ventilatory mechanism due to muscle paresis, flail chest, pneumothorax, airway obstruction, and extreme dyspnea; severe hypertension and cerebrovascular accidents; hypersensitivity.

Doxapram is not recommended for patients 12 years of age or under because studies to evaluate its safety and efficacy have not been performed.

Warnings—Doxapram is an analeptic agent; it is neither an antagonist to muscle relaxant drugs nor a specific narcotic antagonist. Since doxapram has an acid pH, it should not be mixed with alkaline solutions such as thiopental sodium.

Since narcosis may recur after stimulation with doxapram, care should be taken to maintain close observation until the patient has been fully alert for 1/2 to 1 hour. (Duration of drug 5-12 minutes.)

Doxapram is an adjunct to well-accepted supportive measures and resuscitative techniques. It may not stimulate adequate spontaneous breathing or provide sufficient arousal in patients who are severely depressed with CNS depressant drugs.

When doxapram is administered to postoperative patients or to patients in a state of narcosis with chronic pulmonary insufficiency, oxygen should be administered concomitantly. Failure to do so may result in further oxygen debt and more severe dyspnea due to the increased work of breathing.

Doxapram should be administered with great care and only under close supervision to patients with cerebral edema, bronchial asthma, severe tachycardia, cardiac arrhythmia, cardiac disease, hyperthyroidism and pheochromocytoma.

Usage in pregnancy

No adequate clinical studies have been performed to determine the safe use of doxapram in pregnancy. Until further clinical experience has been obtained, the physician must weigh the need against possible risks in using the drug in pregnant patients or in women of child-bearing potential.

Precautions—Recommended dosages of doxapram should be employed and maximum total dosages should not be exceeded. In patients with advanced pulmonary disease with hypoxemia, marked respiratory stimulation increases the work of breathing and may, thus, increase oxygen consumption and carbon dioxide production.

With excessive dosage, hyperventilation induced by doxapram may lead to respiratory alkalosis and hypocapnia with tetany and, theoretically, apnea.

An adequate airway is essential. In order to avoid side effects, it is advisable to use the minimum effective dosage. Monitoring of the blood pressure and deep tendon reflexes is recommended to prevent overdosage.

It is desirable that blood gases (P_{O_2} P_{CO_2} O_2 saturation) be monitored to assess the effectiveness of respiratory stimulation.

Intravenous barbiturates, oxygen and resuscitative equipment should be readily available to manage overdosage manifested by excessive central nervous system stimulation. Slow administration of the drug and careful observation of the patient during administration and for some time subsequently are advisable to insure possibility of post-stimulation respiratory depression must be kept in mind. In patients who have been lightly curarized, doxapram may temporarily mask the residual effects of muscle relaxant drugs.

Doxapram should be administered cautiously to patients receiving sympathomimetic or monoamine oxidase inhibiting drugs, since a synergistic pressor effect may occur. It should likewise be used with care in post-operative patients with marked dyspnea due to obstructive pulmonary emphysema, acute or chronic asthma, profound metabolic disorders, severe to moderately severe hypertension, increased cerebrospinal fluid pressure, head injury and acute agitation.

Since doxapram may stimulate basal gastric secretion, it should be used with care in patients with peptic ulcer disease and in patients undergoing gastric surgery.

Vascular extravasation or use of a single injection site over an extended period should be avoided since either may lead to thrombophlebitis.

Hypocapnia accompanying forced ventilation is a potent stimulus to cerebral vasoconstriction; it may be postulated that some element of risk may exist from reduced cerebral blood flow following prolonged and intensive hyperventilation.

Since an increase in epinephrine release has been noted with doxapram, it is recommended that initiation of therapy with this respiratory stimulant be delayed for at least 10 minutes following the discontinuance of anesthetics known to sensitize the myocardium to catecholamines, such as halothane and cyclopropane.

As with other intravenous preparations, all precautions should be taken during administration of doxapram to insure that injection is made directly into a suitable vein; extravasation, and inadvertent intra arterial injection should be avoided.

Adverse reactions—The following adverse reactions have been reported: *Central and Autonomic Nervous Systems.* Hyperactivit feeling of warmth, sweating, muscle tremor clonus, increased deep tendon reflexes, dizziness, muscle spasticity, pyrexia, confusion, paresthesia, pupillary dilatation pilomotor erection, headache, bilateral babinski, fasciculation and carpopedal spasm. A grand mal seizure occurred 95 minutes after drug administration in a known epileptic patient who was on anticonvulsant medication.

Respiratory. Cough, dyspnea, laryngospas bronchospasm and hiccough.

Cardiovascular. Hypertension, sinus tachycardia, bradycardia, extrasystoles, lower T-waves, premature ventricular contractions, irregular heart rhythm, tightness in chest. Although a mild to moderate increase in blood pressure is no infrequent, such an increase may occasionally be of concern in hypertensiv patients.

Gastrointestinal. Nausea and/or vomitin salivation, stimulation of lower bowel, sour taste.

Genitourinary. Urinary retention, stimulation of urinary bladder with spontaneous voiding.

Miscellaneous. Pruritus, thrombophlebit

Laboratory Determinations. A decrease in hemoglobin, hematocrit, or red blood cell count has been observed in postoperative patients. In the presence of pre-existing leukopenia, a further decrease in WBC w observed following anesthesia and treatment with doxapram hydrochloride Elevation of BUN and albuminuria have been observed.

In some of the cases cited above, the patients had received multiple drugs concomitantly, thus preventing an absolute judgment as to the role of doxapram in these reactions.

Dosage—For complete information concerning dosage and administration s package insert.

Supply—Dopram (doxapram hydrochloride) is available in 20 cc rubb stoppered vials containing 20 mg/cc, wi chlorobutanol 0.5% as the preservative.

The AN·TROL™ Circle System Is Here

...and suddenly tidal volume has a new significance

The AN·TROL system is a complete circle providing a new standard of performance in anesthesia delivery. For the first time, a single system offers:

- A separation of tidal volume resulting in
  —preferential exhaust of alveolar gas
  —conservation of reusable patient dead space gas
- Full utilization of fresh gas—no waste
- Improved efficiencies regardless of rate of inflow
- Reduction of hazards of cross infection
- Adaptability to existing anesthesia machines

With the unique AN·TROL design, the exhaust of fresh and dead space gases is delayed until alveolar gas has been expelled. This engineered efficiency allows the AN·TROL circle to be used as a non-rebreathing system for the average adult patient at a moderate five liter inflow. At lower flows, efficiency is maintained by employing the AN·TROL in-line CO_2 absorber.

The convenient, single-use patient circle, the practical CO_2 absorber canister, the high quality, durable control arm—all combine to make the AN·TROL Anesthesia Circle System* the new symbol of excellence in anesthesia delivery.

For descriptive literature about the system or information about the AN·TROL free loan movie, write or call:

Propranolol and Surgical Anesthesia

JOEL A. KAPLAN, MD*
RONALD W. DUNBAR, MD†
Atlanta, Georgia‡

The potential danger of anesthetizing a patient on beta-adrenergic blockade therapy has long been recognized. The cases of 73 patients taking propranolol and anesthetized for noncardiac operations were reviewed with regard to preoperative administration of propranolol and intraoperative and postoperative complications. Of these patients, 72 percent took propranolol to within 24 hours of operation and 85 percent took it to within 48 hours. The mean dose of propranolol was 77 mg/day (range, 10 to 320 mg/day). Anesthetic techniques and agents included enflurane, halothane, N_2O-narcotic-relaxant, and spinal anesthesia. There were only three episodes of hypotension, all of which responded to a decreased depth of general anesthesia, IV fluid administration, and, in one patient, a small dose of a vasopressor. There were no intraoperative or postoperative deaths. It is concluded that if propranolol is indicated for medical control of the patient's symptoms, it need not be discontinued before surgical anesthesia.

PROPRANOLOL is an important drug in the medical management of patients with angina pectoris, hypertension, cardiac arrhythmias, thyrotoxicosis, pheochromocytoma, and obstructive cardiomyopathies.[1] An increasing number of patients can be expected to present for surgical anesthesia while taking this beta-adrenergic blocking agent.

Autonomic nervous system activity has been shown to be a major factor in maintaining circulatory integrity during anesthesia. Price and associates[2] reported a direct correlation between the depth of cyclopropane and ether anesthesia and plasma catecholamine levels. Sympathetic nervous system activity antagonizes the direct cardiovascular depression produced by general anesthetic agents such as cyclopropane, ether, fluroxene, and ketamine. There is also some evidence that sympathetic activity may be important with such other agents as halothane and morphine.[3,4]

The theoretic potential dangers of anesthesia in patients taking beta-adrenergic blocking agents have been reported since 1964.[5,6] The contention in these articles has been that beta-adrenergic blockade would result in profound myocardial depression during general anesthesia. However, there have been no reported studies of large groups of patients taking propranolol who have undergone anesthesia for noncardiac operations. The purpose of this study is to report our experience during 1 year with patients taking propranolol and coming for noncardiac surgical procedures.

METHODS

A series of 73 patients undergoing operations between January 1974 and January 1975 was reviewed for preoperative administration of propranolol and intraoperative or postoperative complications. Patients were analyzed as to age, dosage of and reason for taking propranolol, time between

*Assistant Professor of Anesthesiology, Director, Division of Cardiothoracic Anesthesia.

Paper received: 5/15/75
Accepted for publication: 6/2/75

discontinuing propranolol and induction of anesthesia, type of surgical procedure, anesthetic agents, and complications.

Patients were divided into four groups, according to how long their propranolol had been discontinued before induction of anesthesia:

Group I, <12 hours

Group II, 12 to 24 hours

Group III, 24 to 48 hours

Group IV, >48 hours

All complications were recorded during the anesthetic procedure, in the recovery room, and postoperatively. Hypotension was defined as a systolic blood pressure 20 percent below the lowest recorded preoperative blood pressure, and significant bradycardia was considered below 50 beats/min. Arrhythmias recorded were those occurring during the operative procedure.

Anesthetic technics included general, spinal, and local anesthesia with IV sedation. Of the patients who received general anesthesia, 90 percent were induced with thiopental (2 to 4 mg/kg IV), while 10 percent were induced with the inhalation agent itself. Anesthesia was maintained with 50 to 60 percent N_2O, and either halothane, enflurane, or narcotics and relaxants. Tetracaine 1.0 percent was used for all spinals. Lidocaine was administered for the two procedures under local anesthesia; both these patients were sedated with diazepam.

RESULTS

Seventy-two percent of the patients took propranolol within 24 hours of operation and 85 percent took it within 48 hours (table 1). The mean dose of propranolol was 77 mg/day (range, 10 to 320 mg/day). The larger doses were taken by those patients who continued the drug closest to operation. Most patients in groups III and IV were taking less than 80 mg/day, while most in groups I and II were taking 80 to 160 mg/day (fig 1). Only 2 percent of the group-I patients were taking over 160 mg/day.

II	13	8	4	
III	4	3	2	
IV	2	6	3	
Total	31	26	15	1

Most patients (77 percent) were receiving propranolol for the treatment of either angina pectoris or cardiac arrhythmias (table 2). Propranolol was taken by 20 percent for control of hypertension, and 1 patient was being treated for hyperthyroidism.

All types of surgical procedures were included except cardiac (table 3).

Enflurane was the most frequently used anesthetic agent (fig 2), followed in order by balanced N_2O-narcotic-relaxant, halothane, spinal, and local. Local anesthesia with sedation was used only in 2 patients in group I. In this series, no cyclopropane, ether, or fluroxene was used, since these are flammable.

The three episodes of hypotension (table 4) involved 1 patient each in groups I, II, and IV; all responded to decreasing the

depth of general anesthesia, IV fluid administration, and a small dose of vasopressor in one. Two of these patients were taking between 80 to 160 mg/day of propranolol and one was taking less than 80 mg/day. Two were anesthetized with a balanced anesthetic technic consisting of N_2O, morphine, and pancuronium; enflurane-N_2O was used for the other. Two other patients developed nodal rhythms during enflurane anesthesia; in one case, this was converted to a regular sinus rhythm by 0.4 mg of atropine.

One patient showed a subendocardial myocardial infarct on a postoperative ECG. He had been taking 160 mg/day of propranolol for angina pectoris until 18 hours before operation and had had a myocardial infarct 2 years previously. This patient, 64 years old and weighing 80 kg, had been premedicated with 5 mg of morphine, 10 mg of diazepam, and 0.4 mg of atropine IM 1 hour before arriving in the operating room. Upon arrival, his heart rate was 48 beats/min, increasing to 60 beats/min after 0.4 mg of atropine IV. He had an otherwise uneventful general anesthesia with a thiopental induction and maintenance with enflurane-N_2O. His postoperative course was smooth, and he was discharged in satisfactory condition.

There were no intraoperative or postoperative deaths in this series.

DISCUSSION

When the potential dangers of general anesthesia and antihypertensive agents were first reported in 1955, it was recommended that these agents be discontinued 2 weeks before operation.[7] Since then, studies by Ominsky and Wollman[8] and by Prys-Roberts and coworkers[9] have clearly shown that hypertensive patients should be continued on their therapy until the time of operation.

Patients taking propranolol are in an analogous situation. If the patients require the drug for the control of their disease, they may safely be continued on it until within 12 hours of (noncardiac) operation, as this study demonstrates.

In 1964, Craythorne and Huffington[10] reported that propranolol administered to dogs anesthetized with halothane produced minimal cardiovascular effects. The only significant change was a decrease in heart rate. Other studies in dogs and patients have shown that IV administration of beta-blocking agents can lead to hypotension and decreased cardiac output.[11-18] However, in all these studies, the beta-blocking agent has been given IV during general anesthesia. The anesthesiologist giving an anesthetic to a patient on chronic (oral) propranolol therapy is in a somewhat different situation. Here, the anesthetic agent can be carefully

administered to the patient, who has a fixed level of beta-blockade. We believe that this is a significant difference and may account for our good results.

The only major complications attributed to preoperative propranolol administration were in 5 patients reported by Viljoen's group,[14] in whom difficulty was encountered in discontinuing cardiopulmonary bypass after coronary artery surgery. These patients had complex operations involving internal mammary artery implantation and a ventricular aneurysmectomy. All these patients had postoperative left ventricular failure, attributed to their propranolol intake. However, other factors, including inadequate revascularization of the myocardium due to the internal mammary artery implant (Vineberg procedure), poor left ventricular function, and myocardial depression secondary to methoxyflurane, may have caused the low output states. On the basis of this small group, Viljoen recommended withdrawal of propranolol for 2 weeks before cardiac surgery. Others have generalized this to suggest withdrawal of propranolol 2 weeks before *all* operations.

Recently, we[15] reported a series of 169 consecutive patients undergoing cardiac operations. Of these, 82 percent had received propranolol to within 2 weeks of operation, and 52 percent received the drug to within 48 hours of operation. The incidence of hypotension and bradycardia was found to be no different in the patients taking propranolol than in those not taking the drug. Two other studies, by Caralps and colleagues[16] and by Moran's group,[17] support our findings.

If propranolol is to be discontinued preoperatively, the dose should be slowly tapered, not abruptly stopped, as sudden withdrawal can lead to myocardial infarction in the patient with ischemic heart disease.[18,19] We believe the 1 patient in group II whose ECG showed a subendocardial myocardial infarct postoperatively may have sustained the infarction preoperatively after discontinuing propranolol. This would account for his significant bradycardia upon arrival in the operating room. Fortunately, he tolerated the general anesthetic quite well.

Evans and Shand[20] have shown the half-life of propranolol to be 3.4 to 6 hours after discontinuing chronic administration in normal man. Faulkner and associates[21] reported that propranolol disappears from the plasma and atrium in 24 to 48 hours. Studies by Faulkner[21] and by Kaplan[15] of myocardial contractility, using systolic time intervals, have shown that the preejection period and the preejection period/left ventricular ejection time (PEP/LVET) intervals return to normal 24 to 48 hours after discontinuing the drug.

However, since propranolol decreases myocardial contractility, cardiac output, and heart rate, the anesthesiologist must understand the pharmacology of beta-adrenergic blockade and its treatment, if patients are to be continued on the drug until operation. Hypotension during anesthesia should be treated by decreasing the depth of general anesthesia, increasing IV fluid administration, altering surgical manipulation and position of the patient, and administering vasopressors such as ephedrine, as required. For bradycardia, atropine should be given to reduce vagal tone.

In the unlikely event that these steps do not reverse the situation and it is felt that the beta-blockade is contributing to the condition, specific treatment of the beta-blockade should be undertaken (fig 3). An isoproterenol drip can be used to directly compete for the beta receptor; however, larger doses than usual will be required. In cardiac patients, we have used doses in the range of 5 to 20 μg/min. Glucagon has a separate receptor site on the cell wall and releases adenyl cyclase to produce cyclic-AMP independent of the beta-receptor.[22] We have used 5 to 10 mg as an IV bolus, followed by a 1 mg/min via IV drip. Finally, $CaCl_2$ and digitalis work intracellularly at the level of the contractile proteins to improve myocardial contractility;[23] 250 to 1000 mg of $CaCl_2$ given slowly IV will effectively bypass beta-adrenergic blockade.

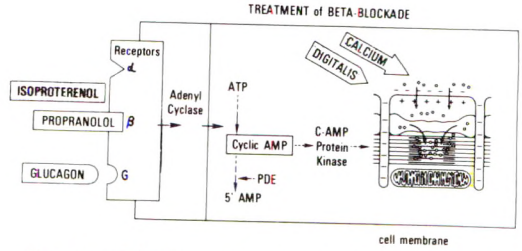

FIG 3. Diagrammatic representation of beta-adrenergic receptor blockade and its treatment. The block can be competitively antagonized with isoproterenol or bypassed with glucagon, calcium, or digitalis.

CONCLUSIONS

Patients requiring propranolol to within 24 to 48 hours of noncardiac operations can be safely anesthetized. Therefore, should the drug be determined to be necessary for medical control of the patient's symptoms, it should not be discontinued many days before surgery. However, as in all anesthetic procedures, the anesthesiologist should have a thorough knowledge of the pharmacology of all drugs taken by his patient and be prepared to cope with any untoward response.

Visual Communication: Clarity in Lecture Slides Revisited

STANLEY J. McCOMB
Rochester, Minnesota

DESPITE the numerous articles related to the lack of legibility of lantern slides shown at medical and scientific meetings and to the definite need for improvement in this vital area of visual communication there continues an amazing, almost callous disregard of some of the fundamental requirements for the production of satisfactory lecture slides. That visual communication suffers is obvious from such a statement as, "It wasn't the first time I'd seen a gathering of insects palmed off as a collection of data."[1] Or as Fuller[2] reported, of fifty-two speakers before various sectional meetings of the AAAS, twenty-three apologized for their slides.

That deficient visual communication is an all too common fault in slides is implied by the efforts of various national medical and scientific societies to acquaint their speakers with the basic requirements for making satisfactory slides to be shown at their meetings. The American College of Physicians sends its speakers specific recommendations concerning the organization and limitation of data on a slide. The Ethyl Corporation has furnished a pamphlet, *Make Slides Worthwhile*. The American College of Chest Physicians has supplied its speakers with a slide format or template, with typing and spacing suggestions. And it is significant that, in a more wide-ranging field, the magazine *Successful Meetings* recently has added an audiovisual consultant to its staff. This certainly offers evidence that there exists a widespread disregard of available information and means for achieving effective visual communication in lecture slides and that the lack of application of some of the basics in this connection lies almost uniformly with the author. It is to this group that this paper is addressed.

The need for communication is universal. Practically everyone has seen reproductions

FIG 1. American Indian visual. (From Christensen EO: Primitive Art. New York, Thomas Y. Crowell Company, 1955, p 337. By permission of The Studio Publication, Inc.)

of drawings made by primitive peoples to communicate events and ideas, from cave paintings in various parts of the world to the products of our own Indians (fig 1); and one is impressed that their effectiveness is due in large part to directness and simplicity that lead to practically instant interpretation. Now it might justifiably be said that today there is so much more to communicate—but herein lies the challenge: the need for careful evaluation of what needs to be communicated and how best to transfer it to the screen. Despite broad acknowledgment of the effectiveness of slides in communication, it is a fact that they remain an abused, sometimes overused adjunct to a verbal presentation.

Emeritus Head of Section of Photography, Mayo Clinic and Mayo Foundation, Rochester, Minnesota.

Before analysis of their faults, slides should be divided into their main categories. The most common undoubtedly is the statistical or data slide, sometimes called "tabular." Chart and graph slides make up another large group; and then there are slides that may be referred to as "pictorials." This paper will deal primarily with data, chart, and graph slides.

Certainly the foremost complaint is illegibility due to crowding—simply, the incorporating of too much data (fig 2). Kern[3] has said: "Don't put too many data on a single slide, especially irrelevant data. . . . This unhappy mistake is the one most frequently committed: the author is too lazy to construct a brief summary of salient data, so he presents instead a detailed table that will occupy a full page in the printed paper." Other factors affecting legibility are improper letter size in relation to screen-image size and poor organization. Obviously all these are interrelated. Charts may be ineffective because of poor design or layout and—if done in color—because of unsatisfactory color combinations and contrast.

Another major fault is use of material prepared initially as an illustration for publication (fig. 3). This may be quite inappropriate for a slide presentation. In published form such data may be referred to repeatedly for correlation with the text, but a slide usually cannot be given more than a quick one-time appraisal. The average viewer can absorb, understand, and retain just so much data in normal viewing time per slide. What the viewer requires, deserves, and expects is a succinct summary of the material presented verbally, not the step-by-step documentation of investigation. Audy[4] has stated it well: "Slides have three functions: 1, to support the spoken word; 2, to amplify the spoken word; 3, to replace the spoken word." That is, "Some things are much better conveyed by a diagram or chart than by description. . . ." And most certainly, a slide is not intended as a teleprompter!

FIG 2. ". . . and this slide clearly explains the principle underlying this very important concept. Next slide, please. . . ." FIG 3. Mass of data satisfactory for publication but worthless as a slide.

As overcrowding of slides with needless data is criticized by all authors dealing with improvement in lecture slides, what remedies are available? One is condensation and better organization of data. At the Mayo Clinic, Hewitt, striving long ago to improve tabular slides, prepared exhibits demonstrating possibilities inherent in organization and classification of data. "Slides are not essays. You will be present to amplify. . . . Condensation requires deletion of detail." He suggested methods for improvement: restrict data to major points; condense text; classify and isolate (fig 4); and wherever possible, present data in graph form.

When a great volume of data is considered absolutely essential, consideration must be given to reorganization; and if effective consolidation is not possible, the data should be presented in additional sequential slides (fig 5). As to reorganization, one author posed the question of WILL/WON'T, which should be applied to every visual. WILL this image help to make my point? WON'T the

presentation be just as clear without it? This calls for a ruthless assessment of data to avoid possible application (fig 6) of the doggerel of Hewitt:

> His audience yawned, it squirmed and it sighed;
>
> He constantly put too much on a slide.

These general problems impose a need of more specific methods and techniques for their solution. As in many other endeavors, it is best to establish some ground rules before proceeding. The predominant slide form today is the 50-mm size (2 by 2 inches) using 35-mm film in a mask opening of 3:2 ratio (34 by 23 mm) oriented horizontally. Although the 2 by 2 slide can be used in a vertical orientation, this is not recommended, for there is very real risk in some situations of having part of the image extend beyond the upper or lower limit of the screen.

Within the frame described, what will be legible? There are well-established criteria for this. One is derived from the Snellen Test Chart for measuring visual acuity. In effect, for a letter to be just legible the entire letter must subtend an angle of 0° 5′ at the viewer's eye. For example, to subtend

HYPERTENSION EMERGENCIES
Sodium Nitroprusside
Now available as "Nipride" (Roche)
Use: 50 mg per 500 to 1000 ml. of 5% dextrose in water. Cover with aluminum foil. Use only 4 hours. Give i.v. by perfusion pump or micro-drip regulator.
Actions: Direct-acting vasodilator.
Decreases BP within seconds
Decreases PVR
Decreases CO (capitance pooling)
No change in GFR or ERPF
Effects stop within seconds; BP back to pretreatment levels in 1 to 10 min.
Side-Effects: Those of lowering BP too rapidly: Nausea, headache, restlessness, muscle twitching, palpitation.
Thiocyanate is end metabolic product (less than 10 mg/dl is safe concentration during prolonged administration.) One case of hypothyroidism.

an angle of 5′ at the pupil of a viewer 100 feet from the screen, a letter on the screen must be 37 mm (1½ inches) high. A more easily grasped rule, applicable to any size conference room, requires that the maximum viewing distance not exceed six times the

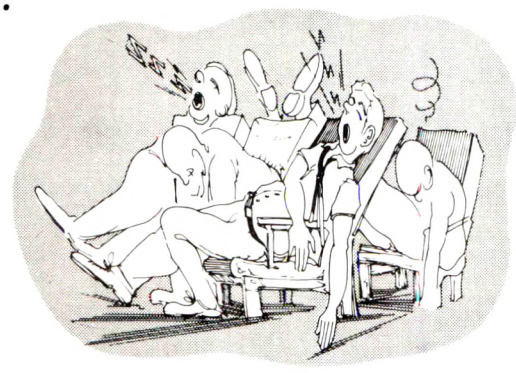

FIG 6. "He constantly put too much on a slide." (Courtesy of John W. Desley, Medical Graphics, Mayo Clinic and Mayo Foundation.)

width of the whole-slide image on the screen. This relation is based on the Room Image Factor (RIF), developed by Maurer from earlier studies by Gage on the optimum projected image size in relation to room length. While this ratio of six times screen width may appear to be conservative, it must be remembered that the viewer for whom it is intended is the one farthest from the screen.

As an aid in achieving greater legibility in slides, use of a standard format for original copy is suggested. Since copy for most tabular slides is prepared on a typewriter, a standard format may be used without difficulty. The format suggested provides for an information area 113 by 75 mm (4½ x 3 inches), and once this area has been determined it may be developed in multiples on a sheet of good quality paper of letter size (fig 7).

Text should be limited to nine double-spaced lines, each line containing no more than 54 total spaces if in elite type or 45 for pica.

Copy prepared in this fashion assures legibility for practically all viewing situations. Characters should be firm and black throughout. Available are special carbon paper ribbons (one-time use only) that yield superior copy. A new—emphasis on *new*—cloth ribbon is an alternative, for which one author adds a suggestion to reverse carbon paper so that the imprint is repeated on the back of the typed copy. Simply, the blacker the copy the better will be the slide.

Turning now to charts and graphs (which may be termed "art work" by some, or "graphics"), all the recommendations offered above for improved legibility apply again—organization of data, restriction to absolute essentials, simplification, and appropriate size and style of letters and numerals for the copy to be photographed. In preparing this type of material, many graphic artists use 229 by 152 mm (9 by 6 inches), again horizontally, as the maximum information area. Using this standard format resolves many problems related to layout,

SUGGESTED TYPING TEMPLATE

Double space all lines.

FIG 7. Template for typing copy.

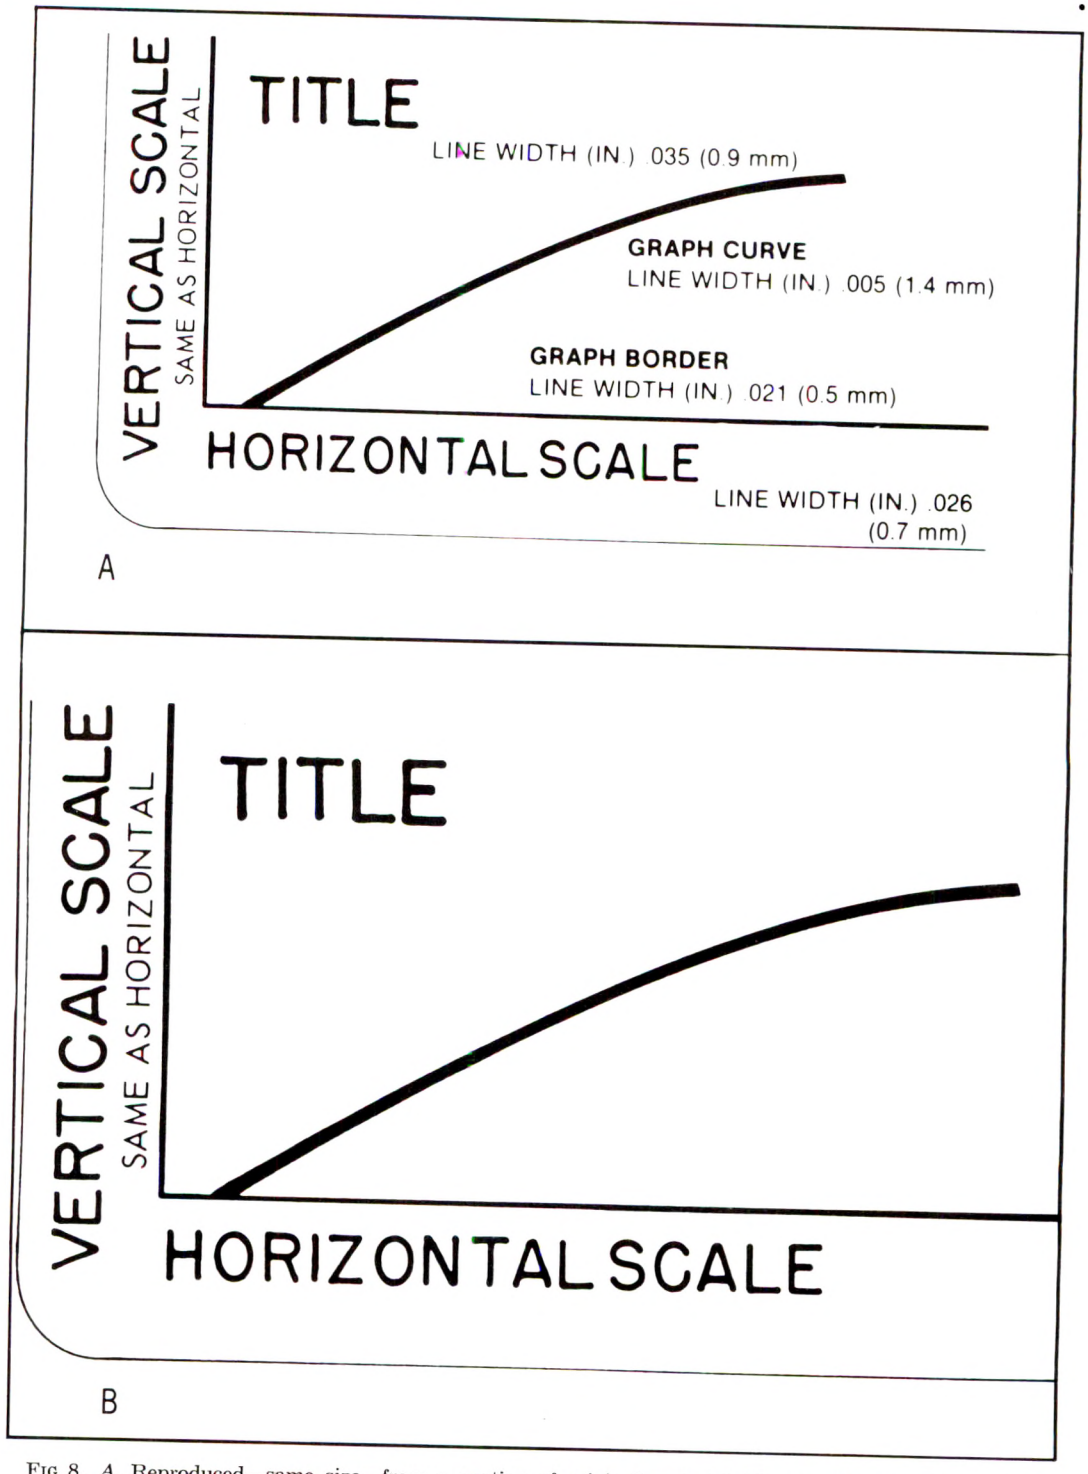

FIG 8. *A*, Reproduced—same size—from a portion of original material 152 mm wide by 101 mm high (6 by 4 inches) with appropriate line and letter widths. Compare with *B*, for original 229 mm wide by 152 mm high (9 by 6 inches), for which letter and line widths must be one-third greater than in *A*. For example: graph curve line width of 1.4 mm becomes 1.8 mm.

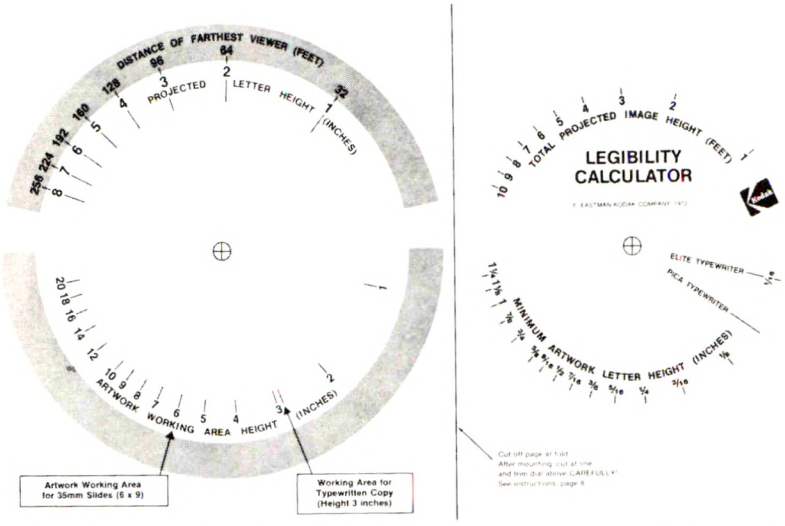

FIG 9. Legibility Calculator. (Reproduced from Kodak Pamphlet S-24: Legibility—Art Work to Screen. Rochester, New York, Motion Picture and Audiovisual Markets Division, Eastman Kodak Company.)

letter height, and line weight (thickness), right on down to the photographic aspects.

From the legibility criteria presented earlier it has been determined that letter height should not be less than 1/25 of the specified copy/image width. It applies to both situations, which means that an "office situation" check of legibility may easily be made. Usually, six times the width of copy would require viewing at about arm's length for typed slides and about double that for charts. The Eastman Kodak Company provides a legibility guide for letter height and line weight for main titles and subheadings (fig 8) and a legibility calculator for quick reference (fig 9).

Information usually is grasped more readily in graph form than in tabular form, and that is what visual communication is all about—comprehension and understanding. Bar graphs (fig 10) and pie charts (fig 11) are particularly effective for comparisons of data. These may be prepared easily from a variety of graphic aids such as pressure-sensitive tapes available in a variety of widths and colors, patterned adhesive overlays, and letters. In this way it is possible to create slides that are more readily perceived.

There does exist some justifiable criticism of the customary black letters on a white background slide, with resultant glare from the large expanse of white. Even so, it is preferable to the "reverse text" slide (white on black). The latter does have an advantage in that the words and numbers, being transparent, can be colored by application of water colors, dyes, or transparent tapes.

A very satisfactory solution to the glare problem is to introduce color in the background. This may be done by photographing

the original copy on high-contrast black-and-white 35-mm film and, after processing for proper density, printing on diazo sheets by exposure to ultraviolet or high-intensity lights. Exposure destroys the dye potential in the diazo sheet where light passes through the negative (the text portions); and as the background receives no exposure, it takes on color from "fuming" (exposure to ammonia vapor). Although diazo sheets are available in a variety of colors, blue has been most widely accepted.

For those who wish to carry through the entire process from original to slide, an easily managed, photographic device the Visualmaker,[5] is available. An Eastman Kodak Company product, it provides for slide making by use of color film for both black-and-white and color originals. There are two standard formats: a 75-mm (3-inch) square and a 200-mm (8-inch) square. Excellent

FIG 12. (Courtesy of John W. Desley, Medical Graphics, Mayo Clinic and Mayo Foundation.)

suggestions for the preparation of originals are provided. If these recommendations are observed, along with suggestions offered earlier, this technique yields acceptable slides.

In summary, slides intended for presentation with a paper require special consideration—a textbook-type illustration will not qualify. Give the second look of appraisal, that of the viewer at the rear of the meeting room. Rethink, reorganize, simplify, and clarify the essential data and prepare them according to accepted legibility standards. Stand tall with viewers (fig 12) for contributing to improved visual communication.

Anesthesia for Transcervical Thymectomy in Myasthenia Gravis

DIGVIJAY S. GIRNAR, MD*
AVRON I. WEINREICH, MD†
New York, New York‡

This review of anesthetic experience in 100 cases of transcervical thymectomy for myasthenia gravis (MG) at The Mount Sinai Hospital (1970-1974) underlines current trends in the surgical management at Mount Sinai, where transcervical thymectomy is the procedure of choice for all patients with nonthymomatous MG and for selected patients with thymomatous MG. The transthoracic approach is now limited to malignant thymomas and tumors not accessible through the transcervical approach. Formerly, patients coming for thymectomy either already had a preexisting tracheostomy, or an elective tracheostomy was performed at the time of thymectomy. Since 1972, none of these patients has had elective tracheostomy at the time of operation, and only four were performed in the postoperative period, patients being intubated orotracheally at the time of operation. The tube is usually removed within 1 hour after completion of thymectomy. All patients are followed in the intensive care unit for 24 hours or longer, under close supervision of experienced personnel aware of the inherent problems and able to assist ventilation at any stage. This approach has greatly changed the postoperative course of this disease.

MYASTHENIA gravis (MG) is a syndrome characterized by undue muscle weakness upon exertion of the involved muscle groups and by a partial return of function either with rest or the administration of appropriate drugs. The weakness may range from diminution of action potentials on EMG of the clinically uninvolved muscles (group I-A in modification of the Osserman classification)[1] to complete motor failure of the involved muscle groups.

Evidence is accumulating that MG is an autoimmune disease[2] and that the purpose of therapy should be directed toward interrupting or ameliorating the autoimmune process. Thymectomy, previously recommended on the basis of empirical observation, now appears to be the treatment of choice for achieving this goal.[3]

The surgical management and the ultimate outcome of the disease largely depend on the care given by a specialized team, which includes internist, surgeon, anesthesiologist, and experienced nursing staff. The anesthesiologist may be faced with unexpected and complex problems, both during the operation and in the postoperative period.

The transcervical approach for thymectomy has replaced the transthoracic in our hospital since 1967 (table 1). The simplicity of this approach has contributed to a dramatic overall reduction in morbidity and mortality in this group of patients,[4] allowing an earlier return to spontaneous respiration, permitting earlier extubation, and avoiding the necessity for tracheostomy. Surgical operation was previously recommended in

TABLE 1

1958-1967	Thymectomy by transthoracic approach: All patients had elective tracheostomies at the time of thymectomy.	251 cases
1967-1971	Transcervical thymectomy: All patients had elective tracheostomy at the time of thymectomy. Transthoracic thymectomy was performed in cases of: (a) Thymoma (b) Preexisting low-lying tracheostomy	200 cases
1972-1974	Transcervical thymectomy: No elective tracheostomy.	151 cases

those patients with severe symptoms who had become refractory to anticholinesterase drugs. As a result of reduced operative mortality and morbidity with the transcervical approach, the indications for thymectomy have been expanded to include the milder cases and those with a shorter history of the disease.[3,4]

Clinical Experience. — At The Mount Sinai Hospital between January 1970 and March 1974, 151 patients underwent thymectomies. One hundred of these, ranging in age from 6 to 70 years and including 36 males and 64 females, for whom records were complete, have been classified[5] according to their myasthenic severity:

Pediatric group:

a. Neonatal—occurs only in infants born of myasthenic mothers and is self-limiting.

b. Juvenile—may develop at any time from birth to puberty.

Adult group:

1. (a) Ocular myasthenia. This localized form of the disease may be limited to one eye and is characterized by ptosis and diplopia.

2. (a) Mild generalized MG. This group is characterized by slow onset, frequently ocular.

   (b) Moderate generalized MG. Onset is gradual, with ocular presentation progressing to a severe generalized involvement of bulbar and skeletal musculature and with involvement of respiratory muscles.

3. Acute fulminating MG. Rapid onset of severe bulbar and skeletal muscle weakness with involvement of respiratory musculature.

4. Late severe MG. Severe myasthenia develops at least 2 years after the onset of group 1 or 2 symptoms. Progression of the disease may be sudden or gradual.

ANESTHETIC MANAGEMENT

Preoperative Visit.—This is mandatory for the attending anesthesiologist, since these patients as a group tend to be anxious and aware of their condition, and require assurance and full explanation of the procedure. The need for possible postoperative ventilatory support is explained carefully, and whenever possible the patient is introduced to the members of the intensive care unit who will be caring for him. Sedation is prescribed as necessary, the results of the routine investigations are checked, and any deviations from normal in any of the parameters are corrected prior to operation. A respiratory system review should observe the absence of chest infection and include an estimate of exercise tolerance. Emergency drugs and equipment for intubation are kept within reach.

Premedication.—Half of the morning dose of pyridostigmine is given in mild cases (classes 1 and 2) while in more severe cases, the regular morning dose is prescribed IM. Atropine (0.4 to 0.6 mg IM) is given 1 hour before operation. Various combinations of narcotics, barbiturates, or tranquillizers are used.

Induction.—On arrival in the operating room an IV infusion is started; temperature, ECG, and blood pressure are recorded. A sleep dose of sodium thiopental is given, and halothane or enflurane and N_2O-O_2 are given by mask. Once the patient is well anesthetized and the masseters are relaxed, an attempt is made to visualize the vocal cords,

which are then sprayed with 4 percent lidocaine, and the patient is subsequently intubated with a nonkinkable anode tube.

Should there be any difficulty with intubation, anesthesia is deepened and a further attempt at intubation is made. After auscultation has determined that both sides of the chest are being aerated, the tube is secured and the patient is mechanically ventilated. The eyes are taped and the head is fully extended with sheets under the shoulders. The patient is positioned and draped as for a standard head and neck procedure. The surgeon stands behind the patient's head.

The incision is made across the suprasternal notch, and a fiberoptic light is used to aid in visualization of structures deep to the sternum. Once the bilobed thymus has been removed entirely and hemostasis achieved, the wound is closed in layers and drained with a Hemovac.®[4] At the end of the procedure, an attempt is made to reestablish spontaneous ventilation and the patient is taken to the intensive care unit, breathing 100 percent O_2 spontaneously via the endotracheal tube or is assisted with an Ambu® bag.

Postoperative Procedure.—On admission to the intensive care unit (ICU), respiratory data are collected on all patients. Routinely, a Wright respirometer is used and tidal volume, minute volume, vital capacity, and respiratory rate are recorded. Blood is drawn from the radial artery for Pao_2, $Paco_2$, pH, base excess, and hematocrit, to establish baseline data. Chest x-rays are routinely taken on ICU admission and thereafter as indicated by the patient's condition. If secretions are copious and troublesome due to the bronchorrhea produced by the anticholinesterase therapy, combined suctioning and chest physiotherapy is employed and atropine administered IV, as needed.[6]

Depending upon the severity of the disease, those who were breathing spontaneously preoperatively are usually extubated once they are fully awake and exchanging adequately, usually within the 1st hour after operation. A resuscitation tray is kept at the head of the patient's bed and a ventilator is kept beside it, in case the patient's condition should deteriorate.

Some patients have had to be weaned off the ventilator gradually, depending on their clinical response. The psychologic aspects cannot be stressed too strongly, as these patients as a group are very dependent on the medical and nursing staff and require constant reassurance and encouragement.

Where secretions remain troublesome, and particularly where respiratory infection supervenes, a tracheostomy may be indicated after 48 hours. Since 1972, 4 of our patients have required postoperative tracheostomy. In the postoperative period, once the patients are fully awake, the preoperative anticholinesterase regime is continued IM. Once they are able to swallow, oral therapy is reinstituted as indicated.

Of the 100 patients studied, all but one received thiopental for induction and the majority were intubated with halothane. Seven patients were given enflurane, introduced late in the series. Positive-pressure ventilation was maintained routinely during operation. Ninety patients of this group were able to breathe spontaneously at the end of the surgical procedure, and 92 were extubated within 2 hours after operation. The average duration of surgery was 2 hours.

DISCUSSION

The value of thymectomy in the treatment of MG is well established, and remissions are generally permanent, the percentage of patients in remission increasing yearly. Of 111 nonthymomatous myasthenic patients followed for 7 years, 90 percent were in remission or showed marked improvement.[2]

It is generally accepted that the thymus is responsible for the formation of antibodies. The thymic hyperplasia with germinal center formation and/or spindle-cell thymomas is a consequence of this increased thymic activity.[2] The theory to which we currently subscribe is that the stable remission produced by thymectomy is presumably the result of eliminating the germinal centers responsible for the formation of these antibodies.[2] The nature of the autoimmune response at the myoneural junction is still not clear. Though spontaneous remissions do occur in myasthenics on medical treatment, they are generally followed by relapses.

In this institution from 1958 onward, all patients admitted for transthoracic thymectomy either had had a preoperative tracheostomy or underwent routine tracheostomy at the time of thymectomy, to cope with secretions and offer a route for ventilatory

assistance. In 1967, the transcervical approach was introduced, and the routine performance of elective tracheostomy was continued until 1971. Since 1972, no elective tracheostomy has been performed. Experience in recent years, with prolonged oral and nasotracheal intubation, using nonreactive materials and low-pressure cuffs, has markedly reduced the incidence of tracheal erosion and has influenced us to adopt this method. This development went hand in hand with the establishment of an ICU, where a team skilled in the care of such patients provides the single most important factor in determining a successful postoperative outcome.

Though complications of transcervical thymectomy are rare, they need to be mentioned:

1. Hemorrhage involving the great vessels of the mediastinum at the time of operation.

2. Pneumothorax: A small pneumothorax is not uncommon; an immediate postoperative chest x-ray will reveal its extent and indicate the need for aspiration.

3. Air embolism is a remote possibility, but none occurred in this series and none has been reported.

Narcotics, sedatives, or tranquilizers as premedication should be used with circumspection, to avoid respiratory depression or the ability to cope with secretions.

The use of pyridostigmine preoperatively to avoid a respiratory crisis from developing at this time may lead to difficulty in intubation without relaxants in a patient who manifests no weakness. The excessively deep levels of halothane required for intubation frequently produces an undesirable fall in blood pressure. In the 7 cases for which we employed enflurane, we have the impression that earlier and better relaxation of the masseters was achieved, though the laryngeal reflex is not as well obtunded as with halothane. The use of topical 4 percent lidocaine will, however, permit early intubation in these cases. Should the need arise for further relaxation, a small amount of d-tubocurarine (0.5 to 1 mg at a time) may be given until the desired degree of relaxation is achieved.

No attempt is made to reverse the neuromuscular block at the end of the operation, and the patient remains intubated to the intensive care unit. To facilitate intubation, we propose to eliminate the morning dose of pyridostigmine in those patients with mild generalized MG, though many myasthenics are so psychologically dependent that they may still require a placebo.

The myasthenic condition may be worsened by a large variety of drugs having a synergistic effect with the defect in neuromuscular transmission or aggravating the muscarinic effects of anticholinesterase therapy. Some of the more frequently encountered drugs are reviewed in table 2, together with the possible mode of action in this as yet not very well elucidated field.

CONCLUSIONS

Transcervical thymectomy for MG and the routine use of endotracheal intubation with postoperative care in an intensive care unit represents a significant advance. These have all but eliminated the need for tracheostomy and have further decreased the morbidity and mortality in this condition when surgical operation is undertaken in the earliest stages of the disease.

TABLE 2

Drugs to Avoid or Use with Caution in Myasthenia Gravis

1. *Muscle relaxants:* The site of action and the effects of the depolarizing and nondepolarizing agents are well elucidated and should be used cautiously. Synergism occurs with the nondepolarizers and while initial antagonism to the depolarizers occurs, it may be followed by a prolonged apnea in the patients treated with anticholinesterases.

2. *Antiarrhythmic agents:* May produce a profound deterioration in the myasthenic state, quinine[7] and quinidine[8] by decreasing the spread of excitation along the muscle fiber; procainamide[9] by decreasing the amount of acetylcholine liberated at postganglionic endings.

The myocardium may be involved in the disease process, and arrhythmias are not uncommon. In addition, irregularities may occur with the use of halogenated inhalation agents in the presence of large doses of anticholinesterase drugs. Digitalis, diphenylhydantoin, or lidocaine may be safely employed.

3. *General anesthetics:* Have both central and peripheral actions. Ether, enflurane, methoxyflurane have all been used. Ether has a curarelike effect at the myoneural junction; owing to its irritant effect on the tracheobronchial tree, it is generally not recommended, although Foldes[10] has suggested its use in low analgesic concentrations with N_2O-O_2, as its myoneural effects are more transient than those of the nondepolarizing relaxants. Cyclopropane is strongly vagotonic, and together with anticholinesterases may increase the incidence of arrhythmias. No flammables can be used in the presence of diathermy, which is now universally employed.

4. *Local anesthetic agents:* One should avoid high concentrations of ester-linked local anesthetics hydrolyzed by nonspecific cholinesterases of plasma and liver. This enzyme is inhibited by anticholinesterases, and the toxicity of these agents may be significantly increased in myasthenic patients on pyridostigmine bromide, a long-acting anticholinesterase.[10]

5. *Narcotics:* The depressant effects of morphine[11] sulfate are enhanced by anticholinesterase therapy. Judicious use is recommended, especially in the postoperative period, and while there is usually no need for narcotics in premedication, about 15 percent of MG patients have marked painful sensory involvement.

6. *Barbiturates:* Pentobarbital sodium, secobarbital sodium, and phenobarbital sodium have both central and peripheral effects. While they are used both as premedication and for induction, large doses may have an adverse effect on neuromuscular conduction in MG patients by rendering the postsynaptic membrane insensitive to acetylcholine.[12]

7. *Tranquillizers:* Myasthenics are emotionally labile as a group and often need tranquillizers. Chlorpromazine intensifies the effects of d-tubocurarine and gallamine.[13] Meprobamate and diazepam probably depress transmission of nerve impulse in the cord.[14]

8. *Antibiotics:* Streptomycin, neomycin, kanamycin, gentamycin, sulfonamide, and colistin derivatives (Coly-Mycin,® Cleocin®) all reduce the total amount of acetylcholine released. Part of the mechanism lies in their depletive action on calcium, which plays a role in the release of the acetylcholine quanta.[15,16]

9. *Antihypertensives:* Guanethidine, hexamethonium, and trophenium all potentiate the effects of depolarizing muscle relaxants. MAO inhibitors have a similar effect.[17]

10. *Diuretics:* Such agents as thiazides and furosemide have a potassium-depleting effect, thereby enhancing muscle weakness.

11. *Electrolytes:* Low sodium,[18] low calcium, and high magnesium[19] interfere with release of acetylcholine.

Changes in Airway Resistance Following Droperidol, Hydroxyzine, and Diazepam in Normal Volunteers

JAMES E. COTTRELL, MD*
BERNARD WOLFSON, MB, FFARCS†
E. S. SIKER, MD‡

The effects of droperidol, hydroxyzine, and diazepam on airway resistance (AR), functional residual capacity (FRC), and thoracic gas volume (TGV) were compared, using a CPI model-2000 body plethysmograph.

Significant decreases in AR were seen following droperidol and hydroxyzine at all time intervals. A significant increase in AR also was noted 90 minutes after diazepam injection. FRC significantly decreased at 60, 90, 120, and 150 minutes following droperidol, and at 90 minutes following hydroxyzine, while no change was seen following diazepam.

No significant changes in TGV were seen following administration of any of the drugs.

THE armamentarium of the anesthesiologist now includes a large number of psychotropic drugs. Although they are used primarily for their central nervous system effects, the possibility of useful or deleterious effects on other systems must be considered.

Recently, Steen and associates[1] compared the effects of diazepam and hydroxyzine on airway resistance (AR) and thoracic gas volume (TGV) in patients with bronchospastic disease. They found that hydroxyzine significantly reduced both AR and TGV, while diazepam had no significant effect on either parameter.

The present study was undertaken to compare the effects of hydroxyzine, diazepam, and droperidol on AR in volunteers with normal respiratory systems.

METHOD

Eight volunteers, 2 women and 6 men, with normal pulmonary function (FEV_1 greater than 70%, FEV_3 greater than 95%, vital capacity greater than 80% of the predicted), measured with a National Cylinder Gas Pulmonary Function Indicator, took part in the study. Ages ranged from 24 to 29 years and weights from 45 to 80 kg. None of the volunteers had a prior history of bronchospastic disease.

Using a Cardio-Pulmonary Instruments Corporation model-2000 body plethysmograph, AR, simultaneous TGV, and FRC were measured before intramuscular injection of either hydroxyzine (1 mg/kg), diazepam (0.1 mg/kg), or droperidol (0.07 mg/kg). Measurements were repeated at 30, 60, 90, 120, 150, and 180 minutes after drug injection. Each subject was given three injections, one of each drug, with 7 or more days between injections. In addition, one subject received an additional dose of hydroxyzine following the three injections. Neither the subjects nor the investigator knew which drug had been administered.

The plethysmograph consists, in essence, of a sealed box, within which pressure

changes are measured, and a pneumotachygraph, through which the seated subject breathes and from which flow measurements are derived. In addition to box pressure, pressure may be measured at the subject's mouth. Using Boyle's Law, it is possible to calculate lung volumes via the pressure recorded. When flow rates are known, AR may be calculated. Lung volumes measured by this technic include all gas within the chest, including trapped gas, in contradistinction to the more usual closed-circuit helium technic,[2] which measures only gas in full communication with patent airways.

RESULTS

The following results apply to 8 subjects in the hydroxyzine and diazepam group but to only 4 subjects in the droperidol group, because of unpleasant side effects including restlessness, irritability, and insomnia, as previously reported.[3]

1. Airway Resistance.—Hydroxyzine significantly reduced AR at each time interval throughout the study period, the greatest reduction being seen 90 minutes after injection of the agent (table 1). Diazepam caused a significant rise at 90 minutes and droperidol was followed by a significant reduction at each time interval, the greatest effect being seen at 90 and 120 minutes.

2. Functional Residual Capacity.—A reduction in FRC followed both hydroxyzine and droperidol, statistically significant at 90 minutes following hydroxyzine and at 60, 90, 120, and 150 minutes following droperidol. Diazepam caused no significant change in FRC (table 2).

3. Thoracic Gas Volume.—Insignificant changes followed administration of hydroxyzine, droperidol, and diazepam (table 3).

DISCUSSION

The reciprocal of resistance is conductance. It follows that conductance increases as lung volume increases. If conductance is divided by lung volume, conductance/liter

180	5215 ± 310	0.35	5281 ± 313	0.49	4840 ± 401	0.25

is obtained, and this is perhaps the most valid measurement to use when assessing effects on AR, as changes due to lung volume are eliminated. Because lung volume and resistance were decreasing at the same time in this study following hydroxyzine and droperidol, changes in conductance/liter were very marked, as seen in the figure.

There has been much discussion in the literature about the respiratory effects of these drugs, especially alterations in the CO_2 response curve; however, little information is available regarding their effect on bronchiolar smooth muscle tone. Steen found negligible the effect of diazepam on AR in asthmatics, while Heionen and Muittari[4] reported subjective improvement in asthmatics but no change in AR.

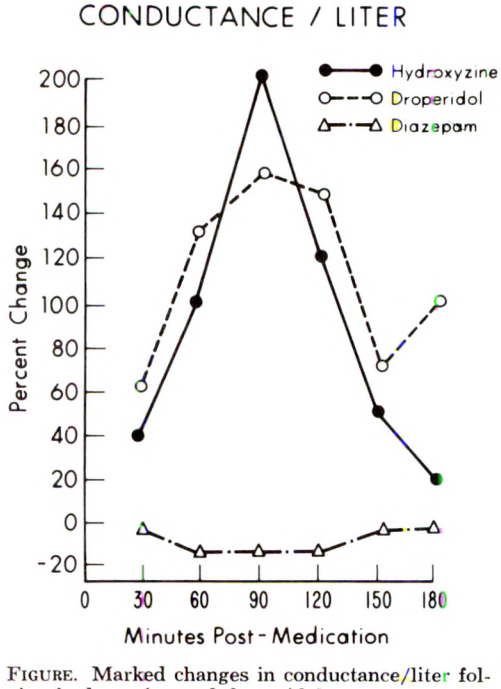

FIGURE. Marked changes in conductance/liter following hydroxyzine and droperidol.

When used alone, droperidol has been shown by MacDonald and coworkers[5] to be devoid of significant respiratory effects, Stocker[6] reported that droperidol had no appreciable effects on bronchial size, and several studies[7-9] have suggested that droperidol may have alpha-adrenergic-blocking properties. Both beta- and alpha-adrenergic receptors are thought to be present in bronchial smooth muscle. Stimulation of beta receptors and treatment with alpha-blocking agents cause bronchodilation.[10] These responses might explain the marked increases we found in conductance following droperidol administration.

The most outstanding effect of hydroxyzine on respiratory parameters is that already referred to by Steen's group. It is of some interest that the maximum effect on conductance/liter reported by Steen was an increase of 60%. This must be compared with the present results, where the peak increase was 200%, suggesting that hydroxyzine may be even more effective in dilating normal air channels than spastic ones. No correlation between hydroxyzine and adrenergic effects has been demonstrated.[11]

Steen's study appears to indicate that hydroxyzine is valuable in the asthmatic patient. However, its value in the normal patient depends on the alterations produced in the closing volume (CV)/FRC ratio. Much attention has been paid recently to the concept of CV and its relationship to FRC as a cause of intraoperative and postoperative hypoxemia.

Don and colleagues[12] showed that both the supine position and the induction of anesthesia cause a fall in FRC. Recently they provided evidence to suggest that this alteration in FRC may lead to a reversal of the normal CV/FRC relationship (CV less than FRC) and may thus lead to air trapping, the functional effect of which is impairment of gas exchange.

It has also been shown recently by Craig and McCarthy[13] that positive-pressure breathing increases both CV and FRC but that FRC is increased more than CV. Both components of FRC—expiratory reserve volume (ERV) and residual volume (RV)—were increased, but the increase in CV was said to be a result of the increase in RV. At the completion of the study, the injection of hydroxyzine was repeated in one subject and spirometric readings were made in addition to the plethysmographic, in an effort to investigate further the fall in FRC, which was found due to a reduction in the RV component.

PLASMA DIAZEPAM LEVELS AFTER SINGLE-DOSE ORAL AND IM ADMINISTRATION. Plasma diazepam levels were estimated by gas-liquid chromatography following a single 10-mg dose given orally (n = 40) or IM (buttocks, 41; thigh, 33) to fit young (mean 32 years) patients for minor gynecologic operations. The highest levels followed oral administration, reaching a peak at 60 minutes. Injection into the thigh resulted in a more rapid initial rise than oral or buttock. The study reinforces an earlier conclusion that, because of unacceptable pain from IM injection, diazepam should be given orally when possible. If IM must be used, deep gluteal is preferable to fascia lattal. *(Gamble, Dundee, Assaf. Anaesthesia 30:164-169, 1975.)*

In each issue of the Journal an article of particular interest and value to anesthesiologists, which has been published elsewhere, will be presented. Primarily the material will contain fundamental basic information which has been presented by anesthesiologists, physiologists, pharmacologists, and others and, on occasion, by commercial firms. In the last instance, these reprintings are not to be construed as an endorsement of the particular commercial firm or its product by Anesthesia and Analgesia—Current Researches.

The Author's Editor

BARBARA G. COX
Consultant, Section of Publications

When a physician or scientist and his editor work together on a personal basis, a creative interaction takes place. The talents of both merge to generate a superior product. And the effectiveness of this symbiotic relationship is enhanced over time. That is, as the author and editor collaborate on more projects, both the quality of the manuscripts and the efficiency of the writing process improve. Ultimately, this means that many hours of the author's time are freed for his scientific endeavors, the institution saves money, and the published material is superior.

FOR the physician or scientist who writes, the editor may be a shadowy being—a faceless entity whose cryptic notes deface the once-tidy pages of a manuscript. Or the editor may be the jealous guardian of a journal, insensitive to the pearls of wisdom an author places before him. Or he may be a disembodied copy editor, capriciously altering words and phrases with no regard for the author's painstakingly conceived prose.

Few authors see editors as editors see themselves—as servants to scientists, to readers, and to the language. Moreover, I suspect that long-buried memories of high school "English composition," with the teacher's impatient criticisms pencilled in the margins, evoke unconscious images in many authors' minds—images of the humorless scholar, more anxious to find fault than to help.

EDITORS: THE GENUS AND THE SPECIES

Editors, like authors, cannot be neatly pigeonholed. They come in different shapes, sizes and temperaments. Indeed, there are two main species of scientific editors, not to be confused with each other. One is the journal or book editor—usually first a scientist and second an editor. This kind of editor rarely revises and polishes a manuscript for publication. Generally, he has been raised to his editorial post on the basis of his scientific eminence and not because he is a student of the language.

On the other hand, the men and women to whom I refer as "authors' editors" or "professional editors" are specialists in biomedical communications. They should be professional helpmates to scientists, that is, partners in communication. These editors work to lighten the load of the scientist who

Reprinted with permission from *Mayo Clinic Proceedings* and the author.

often labors long hours into the night on a manuscript—because he cannot find 15 consecutive minutes to work on it during the day. They realize how difficult it can be for a scientist to disengage himself from the masses of data with which he is intimately familiar and to stand back to view his magnum opus from a reader's perspective. Quite apart from their ability to render an author's prose grammatically correct, skilled editors appreciate the necessity to help an author guide his readers confidently, logically, and persuasively from the beginning of his story to the end.

AUTHOR-EDITOR RAPPORT

Obviously, editorial assistance of this magnitude is not easily given without some interpersonal transactions. For most authors and editors to work effectively as a team, they must know each other. Many institutions provide their scientists with author's editors. But even then, a surprising number of authors fail to make optimum use of this resource, out of apparent ignorance of what a professional editor can do to enhance the quality of their manuscripts and an unawareness of the importance of author-editor rapport to this process. Such authors send their papers through the interoffice mail to the editorial department solely for grammatical and syntactical review. Authors in institutions that have no editorial department are frequently surprised to learn that professional editors even exist. Increasing numbers of authors who are aware of this resource locate free-lance editors* or seek the help of consulting firms in biomedical communications (a new and flourishing business in large, metropolitan areas).

How do these professional editors view their work? Equally important, how do they regard their working relationship with authors? And finally, how can editors help scientists meet their obligation to communicate with their peers on the printed page?

THE PLIGHT OF THE SCIENTIFIC AUTHOR

In addition to their other commitments, most physicians and scientists must write. Part of their professional obligation to the scientific community (and indirectly to society as a whole) is to communicate knowledge to others and to persuade by means of the written word—whether it be in articles for publication, books, grant applications, or reports. Even the letters and memoranda that constitute part of a day's work are important and should be instruments of clear communication. Yet, for a great many scientists, organizing thoughts into a logical sequence and putting them down on paper clearly and effectively are arduous tasks. Thus, countless hours are spent organizing, reorganizing, writing, and rewriting.

Most scientists who publish in professional journals work for large institutions, especially university medical centers. The physician in a large medical center may see patients most of the time, and the basic scientist may spend the largest part of his time in the laboratory, but each must write if he is to reach out to his colleagues—both within the institution and in the scientific community as a whole. Yet, whether we like to admit it or not, the average scientist is not trained to write. Consequently, he tends to tackle the job inefficiently, laboring through draft after draft of a manuscript before he is satisfied. Even then, he may miss his mark—and find out only when a journal referee (presumably knowledgeable in the author's field) turns a manuscript down because he has failed to grasp important points. Or an author may be told that a granting agency has rejected his research proposal on the grounds of scientific inadequacy, when actually the proposal's literary deficiencies have been more at fault. The cost of these efforts to an institution can be staggering, although they are as yet unmeasured.

WRITING AS AN INTELLECTUAL PROCESS

Writing involves a linear thought process, wherein the words are placed on paper by a system of priority. Yet many scientists

*Two major sources of access to free-lance editors in medicine and the basic sciences are the American Medical Writers Association and the National Association of Science Writers.

are relatively nonverbal. That is, much of their thinking is in images, not in words. Einstein, when asked by a colleague whether his thought processes about higher mathematical concepts were carried out in word and number images or in visual images, replied that he definitely thought in visual images.

Writing a scientific report involves a sort of translation process from images to words. Moreover, the scientist must consider many aspects of his work at the same time. Thus, many thoughts and images play across his conscious mind either simultaneously or over a short space of time. He does not always sort his ideas out in linear form, the way ideas must be sorted to be presented most effectively on paper. Consequently, when he sits down at his desk, pen in hand, he may be frustrated because he must make his pen speak the language of the printed page. He finds that he cannot lift the scenes from his head and lay them on paper easily and painlessly.

THE PROFESIONAL EDITOR AS AN INSTITUTIONAL RESOURCE

Most industries, aware of the merits of specialization, hire technical editors and writers to ease the writing burden of their scientists. Industry, traditionally more conscious of where it spends its dollars than universities, pays people to do what they do best—and only that. In this respect, the scientists in an academic setting is less fortunate than his counterpart in industry. He tends to feel that he must be many things to many men: not only scientist but teacher, administrator, and writer. This charade is burdensome to the scientist and expensive for the institution.

Indeed, many medical centers have already recognized the cost-effectiveness of hiring professional scientific editors to assist their faculty. The mere availability of an editor does not guarantee his usefulness, however. A creative interaction must take place between author and editor, and this is a learned process.

THE SYMBIOSIS BETWEEN AUTHOR AND EDITOR

From my experience, the relationship between author and editor is most soundly established and functions best when the author and editor work together on a person-to-person basis. Of course, it is possible to edit an author's work without ever meeting him. Questions can simply be asked in the margins of manuscript pages or sent to the author in an accompanying memorandum. But many times this limits the editing process to superficial revisions. It deprives the editor of access to the author's personal feelings about the paper. Without personal consultation with the author, the editor may be unable to find out where the emphasis in a paper really lies or to fill in gaps that the author unwittingly leaves. Moreover, some authors react defensively to editorial criticisms pencilled on the typed page.

Several steps are involved in a productive author-editor relationship. If an author has never consulted an editor before, he may be unclear about just what an author's editor does. He may hold the common misconception that an editor "corrects the grammar, punctuation, and spelling" in the final draft of the paper. And the final draft of the paper, of course, is the product of weeks of arduous composition, revision, and polishing by the author. Yet one of the main objectives of an author's editor is to persuade the author to let go of his paper before he has invested long, needless hours in successive drafts. Provided that the thoughts are well organized, after the first draft the editor can usually revise and polish the manuscript in a fraction of the time that the author would need.

The author and editor should discuss the paper together briefly before editorial work is begun. Often, in this preliminary talk, an author will reveal major objectives of a manuscript that do not emerge clearly from the text. The author himself may have recognized weak areas in his paper and may be able to point out places where the text has bogged down. This discussion provides the editor with a better picture of the task that lies ahead.

The actual editorial process is a period of intensive analysis and revision—ranging from necessary organizational changes to simple grammatical corrections. The editor helps the author shape his paper for his intended audience, making the information flow logically and clearly. A hundred details must be attended to, as the editor strives to serve simultaneously the author, the gatekeepers of the journal or publishing house, and prospective readers.

A wise editor, as he or she works on the manuscript, remembers that authors can be

very sensitive. Many authors have become conditioned negatively by waspish queries from distant journal editors and anonymous reviewers. An author may be quick to be defensive. So a skillful editor is tactful and constructive in making criticisms. The editor and the author must be on the same team.

A final and, I believe, necessary step in the editor-author interaction during the preparation of a manuscript is a conference when the editing process has been completed. Most scientists dislike writing. Thus, when one of their revised manuscripts is returned through the interoffice mail with an editor's questions attached, it is hardly surprising that many an author simply tucks it away in a drawer for a few weeks. But if the editor sits down with an author to confer about the work, questions can be answered and the work finished without delay.

This conference with the editor accomplishes another goal. The author finds out why the editor made his changes. At minimum, this strengthens the editor-author rapport and facilitates negotiation about final changes, so that the written product represents the synthesis of two minds—the professional scientist and the professional communicator. Ideally, it helps the author learn more about sound scientific writing. It helps him identify weaknesses in his writing style. This kind of interaction enhances the efficiency of the author-editor relationship over time because the author and editor become more familiar with each other's work styles. The groundwork is laid for future cooperation.

HEIMLICH MANEUVER Food choking, although occasionally mistaken for an acute myocardial infarction, can be easily recognized as the victim cannot speak or breathe. The author reports the effectiveness of abdominal infradiaphragmatic pressure (Heimlich maneuver) in clearing an airway obstructed with particulate matter. A quick upward thrust applied on the epigastrum consistently expelled a rubber stopper from endotracheal tubes placed in anesthetized dogs. Apparently, sudden elevation of the diaphragm resulting from abdominal pressure, compresses the lungs and increases airway pressure sufficiently to dislodge obstructing material. The maneuver may also be applied to drowning victims to facilitate expelling aspirated water. Since the original description of this maneuver the author has received 162 reports of food choking or drowning victims who were "saved" by the application of infradiaphragmatic pressure. Vomiting or damage to intraabdominal organs may occur after this maneuver. *(Heimlich H: A life-saving maneuver to prevent food choking. JAMA 234:398-401, 1975)*

Some Gas Machine Hazards and Their Elimination

L. RENDELL-BAKER, MD*

Constant improvement in anesthetic gas machines has been the objective mutually of anesthesiologists, manufacturers, and engineers. Yet the literature continues to report mishaps, sometimes fatal to the patient, due to machine design or function or to "human error." The author reviews some of these hazards and describes proposals for their elimination. He points out that initiative on the part of anesthesiologists is vital in spurring needed changes by manufacturers.

Now that international agreement has been achieved by the ISO TC121† on standard 22 and 15 mm fittings for anesthesia and ventilator breathing circuits, eliminating difficulties due to multiple nonstandard fittings, the time is long overdue for action on gas machine performance and safety standards. Many papers detailing the persistent hazards and failures of our present equipment emphasize the urgency of this work now occupying anesthesiologists and engineers in the US and other countries.

As examples may be cited the recurrent problems with halothane vaporizers, starting with the 1962 report of Safar and Galla,[1] in which "the anesthetist had refilled the jar of the vaporizer inadvertently to a level 4 mm above the 'full' line" so that "the metal inflow tube extended about 1 mm beneath the fluid level causing bubbling of the N_2O-O_2 mixture through the liquid halothane." Three to four times the indicated concentration was delivered under these conditions. Prompt resuscitation saved the patient. The vaporizer was later withdrawn from sale.

This was followed in 1969 by the report of Kopriva and Lowenstein,[2] who described "a previously unreported hazard in the Verni-Trol® vaporizer." When the patient began to move during skin closure, "the halothane flowmeter valve was turned on approximately one quarter turn, but the rotameter bobbin was not seen. The flowmeter control was turned an additional quarter turn, and it was then noted that the bobbin was at the extreme top of the flowmeter. The halothane was turned off and the system flushed with O_2. At this time no pulse or heart beat was detectable." Again resuscitation was successful.

Inspection showed two of five Verni-Trol vaporizers could deliver liquid halothane when the bobbin was at the top of the flowmeter scale and the vaporizer was filled to the "maximum safe level" mark. The manufacturer provided valves to limit the pressure and flow through the vaporizer.

In 1973, Greenhow and Barth[3] reported: "While checking a . . . new Heidbrink Series DM5000 . . . machine prior to use, the O_2 flush was used to fill the circle and reservoir bag. When a breath was taken through the mask, a strong odor of halothane was noticed." With the vaporizer shunt valve open, O_2 flushing caused a rapid rise and then fall of pressure within the vaporizer, producing a surge of 2 to 3 percent halothane vapor through the delivery hose.

FIG 1. Overfilling is prevented in the new Copper Kettle vaporizer (N), by placing the filler on the side of the vaporizer at the maximum safe level. The original model (O) had no mark indicating the maximum safe level, and the filler on the top did nothing to hinder gross overfilling and with it the risk that liquid agent would be delivered to the patient, with lethal effect.

The aim of the design engineer should be to eliminate as many such mechanical hazards as possible. Safety should not depend upon the user's memory and ability to carry out the correct procedure.

OTHER VAPORIZER PROBLEMS

Overfilling Hazard with Vaporizer.—The original Foregger Copper Kettle® had the filler at the top, with no indication of the maximum safe filling level. The latest model (fig 1) has the filler on the side at the maximum safe level, thus preventing overfilling. However, the Ohio Verni-Trol® still has the filler at the top, permitting overfilling; liquid agent would then be delivered to the breathing circuit with potentially lethal results.

Wrong Agent in a Kettle Vaporizer.—There is nothing to prevent an incorrect agent being added, and one is never certain what may be in a vaporizer when it has been filled by many people in a large hospital. This is a very real hazard:

"A 62-year-old white man . . . underwent an aortic-femoral bypass operation . . . with Fluothane®-N_2O-O_2 anesthesia. . . . About 6 hours after the operation, he became agitated and disoriented, with shallow respiration. Cyanosis progressed rapidly . . . the patient became comatose and died 10 hours after operation. *It was subsequently discovered that due to an error trichloroethylene, instead of Fluothane, had been placed in the Copper Kettle.* Histologic examination revealed acute necrotizing tracheobronchitis with focal intra-alveloar pulmonary hemorrhage."[4]

Safety Filling Device.—A detachable standard agent-specific filling and emptying device, like the Pin Safety System, for kettle-type vaporizers (fig 2) could solve the problem. Such a system should automatically empty the vaporizer when detached and prevent refilling until the mechanism is reattached.*

The Combined O_2 Flush-Vaporizer ON/OFF Tap used with the kettle-type vaporizer, this has resulted in accidents varying

*ANSI-Z79 proposed draft standard, Minimum Performance and Safety Requirements for Components and Systems of Continuous Flow Anesthesia Machines.

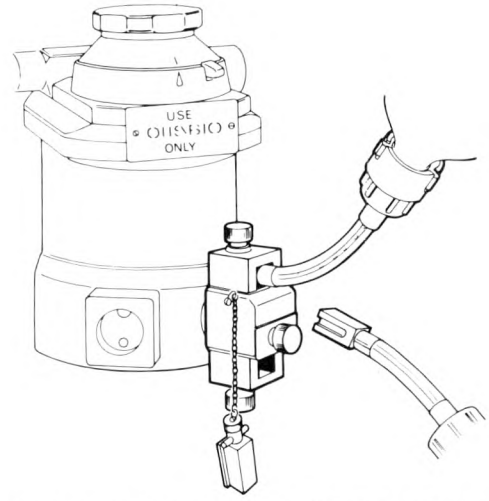

FIG 2. The Fraser Sweatman Pin Safety System. This consists of (1) a pin-indexed filling and drainage port on the vaporizer; (2) a flexible connection with a slot to match the index pin, and (3) a specific thread for the anesthetic agent container at the other end, as these containers have different diameters and threads. Overfilling is prevented also. A detachable version for kettle-type vaporizers is under study. (Fraser Sweatman, Inc illustration.)

from acute anoxia to the patient's awakening. If the vaporizer carrier gas also provides the patient's entire O_2 requirements, as may be necessary for induction with methoxyflurane, failure to turn the vaporizer on again after using the O_2 flush leads to acute anoxia, as the carrier gas is then vented to atmosphere and does not reach the patient's breathing circuit.

Unfortunately, not everyone knows this. The manufacturer became aware of this hazard, but no warning was attached to the vaporizer, and the note in the 1966 vaporizer brochure can hardly be termed explicit. According to the manufacturer's (1966) brochure, "should the anesthesiologist turn the Shunt Valve to the OFF position, he will automatically isolate the vaporizer, and the O_2 previously passing through the vaporizer *will be vented to atmosphere.* It will then be necessary to maintain a flow of metabolic O_2 from a direct O_2 flowmeter to the patient circuit. *By thus acknowledging the performance characteristics of the apparatus, the operator can fully appreciate its efficiency with complete safety.*" This final sentence must rate as a masterpiece of Orwellian "1984" logic!

Solution.—Deliver the carrier gas to the breathing circuit at all times, even though, with the tap OFF, it bypasses the vaporizer. Needless to say, the O_2 flush must always be a separate control.

Foaming of Methoxyflurane in Bubble-Through Vaporizers.—Guzman and Cascorbi[5] reported: "During induction of anesthesia, we turned on 200 ml/min of O_2, to vaporize methoxyflurane in a top-filling 400-ml Copper Kettle. This mixture was delivered to the breathing circle through a clear plastic tube which within seconds began to fill with a foamy, brownish fluid. Immediately the patient was disconnected from the machine. Since he had not inhaled any liquid, he made an uneventful recovery. The methoxyflurane had foamed in the Copper Kettle, filling the kettle and spilling foamy liquid into the delivery tube . . . a speck of sealant applied to the gasket of the lid by a professional maintenance man was responsible for turning the methoxyflurane into a foaming substance. As little as 0.004 mg of Dow-Corning #11 sealant in 100 gm methoxyflurane is enough: it will now foam when agitated. . . . We tested seven anesthetics; foam formed only with methoxyflurane, trichloroethylene, and chloroform. Methoxyflurane developed by far the most persistent foam."

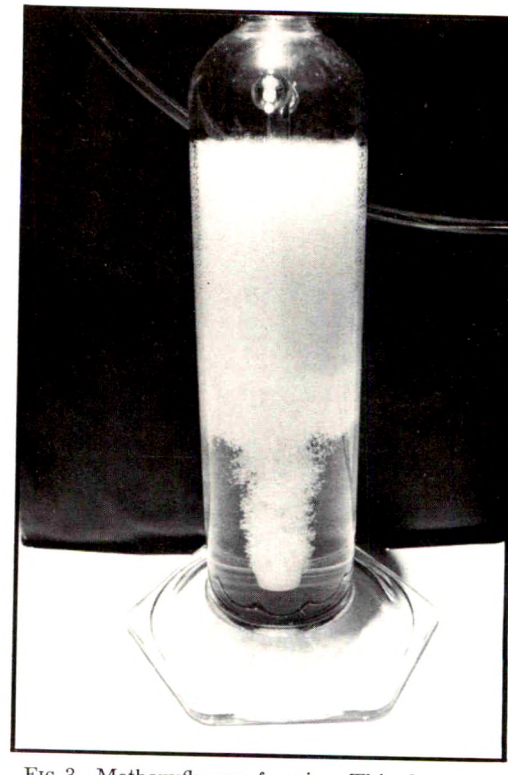

FIG 3. Methoxyflurane foaming. This demonstration by Fraser Sweatman shows the hazard if methoxyflurane in a kettle-type or bubble-through vaporizer becomes contaminated with trace quantities of a silicone compound. The foam produced readily spills over into the breathing system, as Guzman and Cascorbi reported,[5] with potentially lethal results.

Sweatman[6] subsequently reported this foam hazard was first drawn to his attention by Drs. North and Young in 1968. He later became aware that Artusio in 1959, North in 1966, Dornette in 1967, and Young in 1968 had all experienced this problem (fig 3). In 1973, Larsen[7] reviewed the problem in detail. As silicone lubricants and sealants are widely used in industry and one can never be sure they will not be used again somewhere in the assembly, can one still consider the bubble-through type vaporizer safe?

Hazard of halothane in a Pentec vaporizer. According to B. King, quoted in Fraser Sweatman, Inc, literature, halothane placed in a Pentec® methoxyflurane vaporizer in error may result in up to 30 percent halothane vapor being delivered to the breathing circuit, with potentially lethal results. The Pin Safety System filler (fig 2) would prevent this if fitted to all vaporizers, and should also prevent a vaporizer being

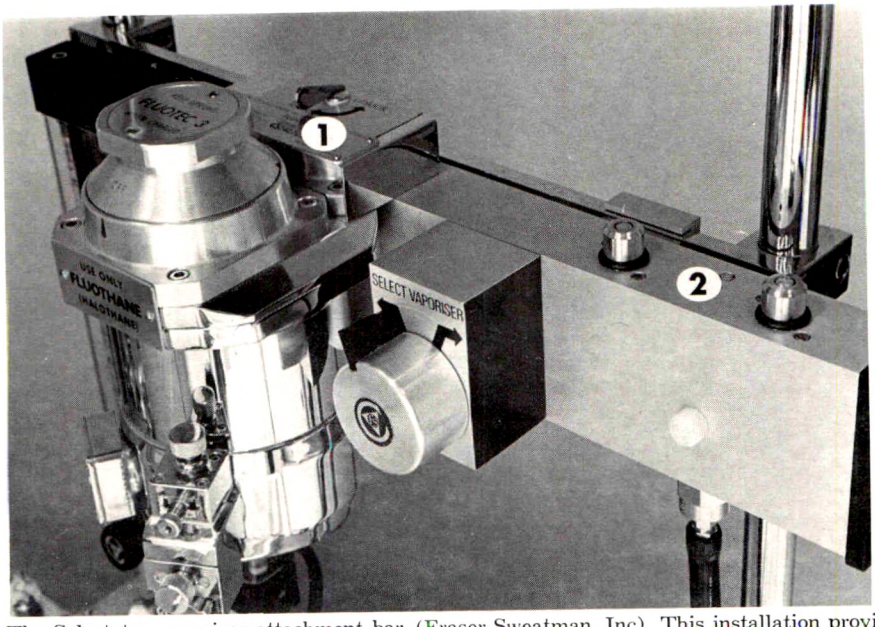

FIG 4. The Selectatec vaporizer attachment bar (Fraser Sweatman, Inc). This installation provides positions for two vaporizers at (1) and (2) but permits only one to be used at any time. Vaporizers may be readily interchanged without the use of tools.

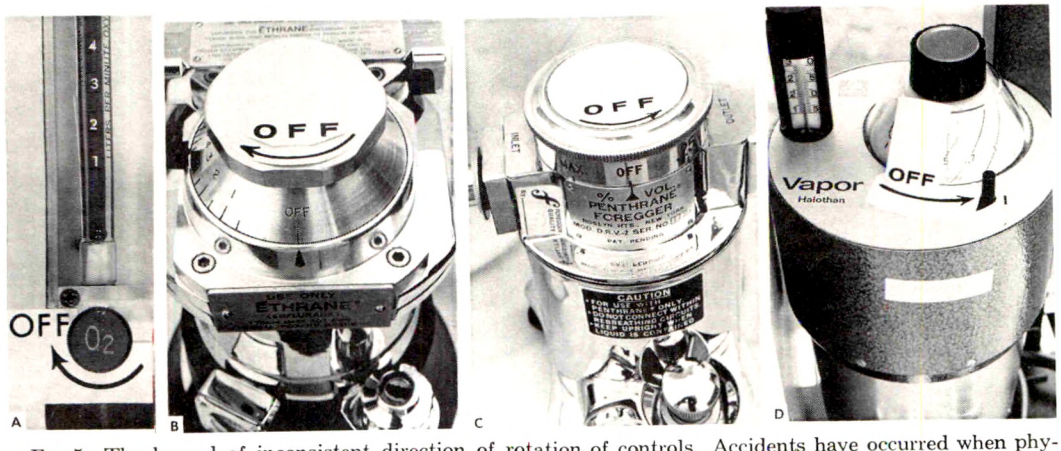

FIG 5. The hazard of inconsistent direction of rotation of controls. Accidents have occurred when physicians familiar with the counterclockwise rotation that turns off O_2 and the Fluotec vaporizer have instinctively turned the control of either a Foregger Fluomatic® or Drager Vapor vaporizer in a counterclockwise direction, under the impression that this was "OFF," when in fact this motion gave the maximum vapor concentration. It would be logical to have the direction of rotation of vaporizer controls consistent with the gas flow control valves, as there are infinitely more of the latter. (A) O_2 flow control valve; (B) Cyprane-Ethrane vaporizer; (C) Foregger Pentamatic® vaporizer; (D) Drager Vapor halothane vaporizer.

drained into a thiopental bottle, with fatal results if later given to a patient as has happened.

Vaporizers must be connected in parallel, for if two vaporizers are opened at the same time, halothane contamination of an in-series methoxyflurane vaporizer can occur.[8] In Murray's report, 7 percent halothane was found in the methoxyflurane! To prevent this, gas must NOT pass through one vaporizer after another. The Fraser Sweatman Selectatec® (fig 4) and the Drager selector systems prevent this contamination.

Should all controls rotate OFF the same way? Clockwise rotation turns OFF the O_2 and the Fluotec®, but turns ON the Foregger and Drager vaporizers—a needless accident hazard. Logically, all vaporizers must turn OFF the same way as the gas-control knobs (fig 5).

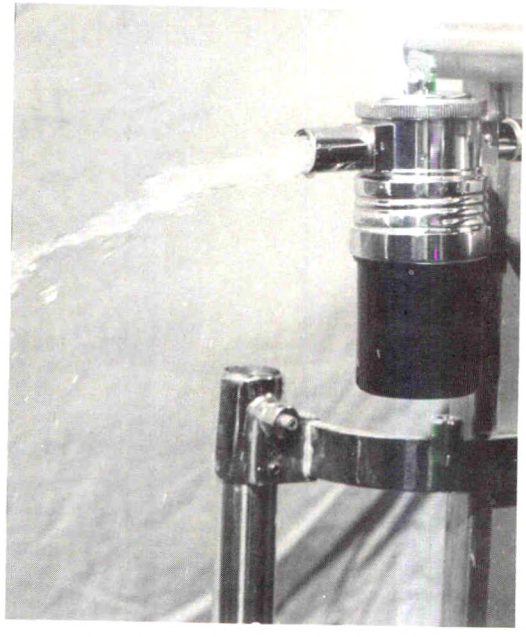

FIG 6. A "flow-critical vaporizer" can be hazardous! If this Foregger trichloroethylene vaporizer is fitted to an Ohio machine, it will empty its contents into the breathing circuit in 2 seconds, as soon as gas flows! The reason: It was designed to be attached to the *male* 15 mm common gas outlet of a Foregger machine, whereas the Ohio machine has a *female* 15 mm fitting at this location. Thus the gas flows through the vaporizer in the reverse direction to that intended by the designer.

A "Flow-Critical" Vaporizer will emit liquid agent if connected to another make of machine the wrong way (fig 6). Hopefully, no new vaporizers will be so designed. Future use of standard index-threaded fittings, permitting the component to be connected only in the correct position on the machine and the correct way, will prevent this.

FLOWMETER HAZARDS

Where's the Oxygen?—Analysis of airplane accidents shows pilot error to increase when layout of controls and instruments is inconvenient or unfamiliar.[9] Imagine the chaos if some cars had the gas pedal on the right and others had it on the left! Yet there is no standard location for the O_2 flowmeter on a machine (fig 7). The Ohio O_2 flowmeter is on the right, the Emerson-Hopkins is on the left, and the older Foregger machines have theirs somewhere in the middle! Happily, it is agreed all future US-made machines will have the O_2 on the right. But most European machines have the O_2 flowmeters on the left; and, as in Germany by law, blue is the standard color for O_2, the possibilities for confusion are legion if US and German equipment ever became intermixed.

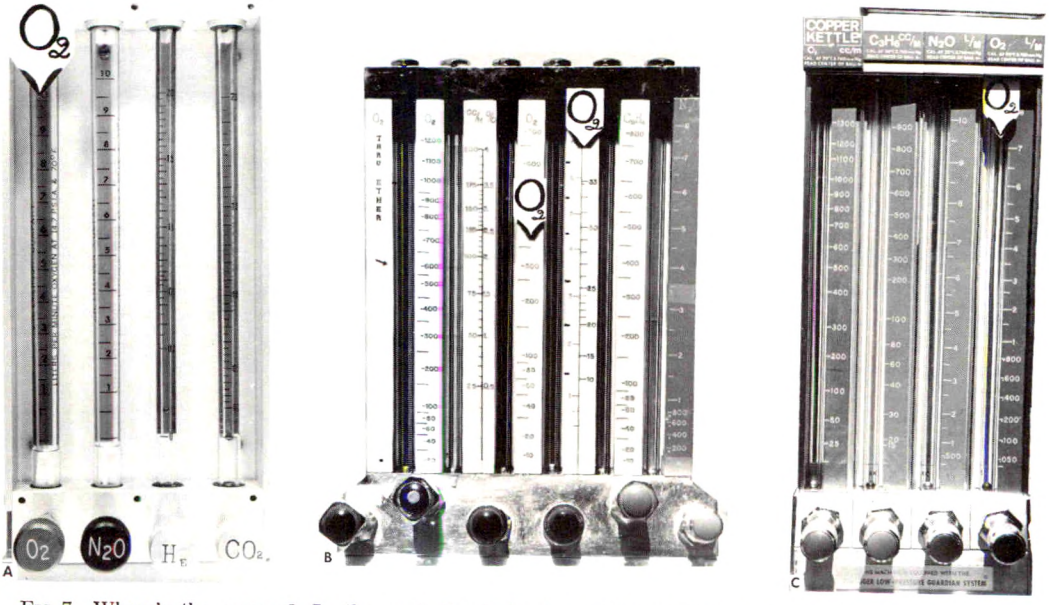

FIG 7. Where's the oxygen? In the past, the lack of a uniform location for the O_2 flowmeter has at best caused confusion and at worst injury or death of a patient. Here (A), the Hopkins-Emerson machine, has the O_2 on the left. In (B), the older model Foregger, two O_2 flowmeters are in the center, with flow controls offset from the scales! In (C), the modern Foregger has its O_2 flowmeter on the right, as will all future new US-made machines, following a recent agreement of US manufacturers.

Eger and colleagues[10] urged that the O_2 flowmeter be next to the flowmeter manifold outlet, to prevent escape of O_2 through a cracked or chipped flowmeter tube before it reached the outlet. Bishop's group[11] reported two such accidents due to this "fundamental fault in the design of the Boyle machine." When a hair crack developed in the cyclopropane Rotameter, without displacement of the broken parts, "the O_2 Rotameter, because of its position on the upstream side of the bank of Rotameters, will indicate a flow of O_2 which, in the event of a leak, will not reach the patient."[11]

Katz[12] and, 5 years later, Liew and Ganendran,[13] reported similar accidents with Drager Tiberius machines; again the O_2 flowmeter was on the left, farthest from the flowmeter manifold outlet. Liew and Ganendran had their problem 4 years after the manufacturing company had indicated that all its future flowmeter manifolds would be designed to deliver the O_2 to the manifold outlet despite any leak through another flowmeter.[14]

Low Flow, High Hazard.—The accidental use of low flows of O_2 when a high flow is intended is a built-in hazard whenever two O_2 flow controls are fitted.[15] Mazze[16] reports "death occurred in a 45-year-old man scheduled for hemorrhoidectomy. The anesthesia machine was equipped with two separate O_2 flowmeters, one calibrated in milliliters, the other in liters. The wrong O_2 flowmeter was used, resulting in 4 L of N_2O being delivered with 200 ml of O_2, rather than 2 L of O_2. Cardiovascular collapse occurred and the patient could not be resuscitated."

Solution.—Provide only one flow control valve for each gas! When low and high flows are required, two flowmeters placed in series are controlled by a single knob.

Separate Tube, Scale, and Float Hazards.—Some manufacturers insist that only by using plain flowmeter tubes and hand calibrating an individual scale for each tube can adequate accuracy be provided. As seven sizes of tube and three different weights of floats are used in differing combinations to provide the desired flow ranges, only a code letter and not the name of the gas is marked on the tube. So if the tubes and floats become separated from their scales, they may easily become mixed. It will not then be obvious that an error has been made unless volumetric checks are made. Though manufacturers caution their personnel not to remove more than one tube at a time, to err is human!

Malfunction of a New Anesthetic Machine.—Walts and Inglove[17] failed to produce satisfactory anesthesia with the salesman's "demonstrator," borrowed while their machine was being repaired. They found that, "by mistake, a small-bore rotameter tube had been used in place of the normally large-bore N_2O tube. No error had been made in the scale. So that, at an indicated flow of 5 L/min of N_2O, the flow was closer to 500 ml." Their problem was not unique, for Kelly and Gabel reported:

The Improperly Calibrated Flowmeter.[18]—"The 20 to 250 ml/min flowmeter to the Verni-Trol of one of our Ohio anesthesia machines was broken. The repairman installed a replacement which included *a new scale, tube and bobbin.* He did not check the flow calibration." When next used, the odor of halothane coming from the system was unexpectedly strong. "With the flowmeter set at 250 cc/min, the measured flow was approximately 1500 cc/min. This would have delivered roughly 6 times as much volatile anesthetic agent as the flowmeter indicated." Even though the repairman installed a complete flowmeter assembly—scale, tube, and float—a potentially lethal error occurred. This, then, is the true price of hand-calibrated accuracy with the present designs.

Chadwick[19] described, due to *transposition of rotameter tubes,* "the delivery of hypoxic anesthetic mixture to 2 patients undergoing general anesthesia for minor procedures. The anesthetic machine was a regularly maintained Ohio Unitrol® 'three-gas' table model." "The rotameter assembly was protected by a thick plastic shield, which also partly obscured the rotameter bobbins when these were at a position of zero gas flow. The machine was . . . used infrequently." It took two visits by the serviceman before the cause was discovered, "that, at a rotameter setting of 5 L/min of O_2, a volume of 400 ml was delivered. When the plastic cover was removed, it was observed that the rotameter tube was absent from the cyclopropane position; it was found to be in the O_2 (D) position." "In this machine, the rotameter tubes were not marked by etching on the glass but by scales fixed to the back of the rotameter panels, and the tubes are plain except for the code letter." Surely it is not too much to ask that this problem be eliminated once and for all

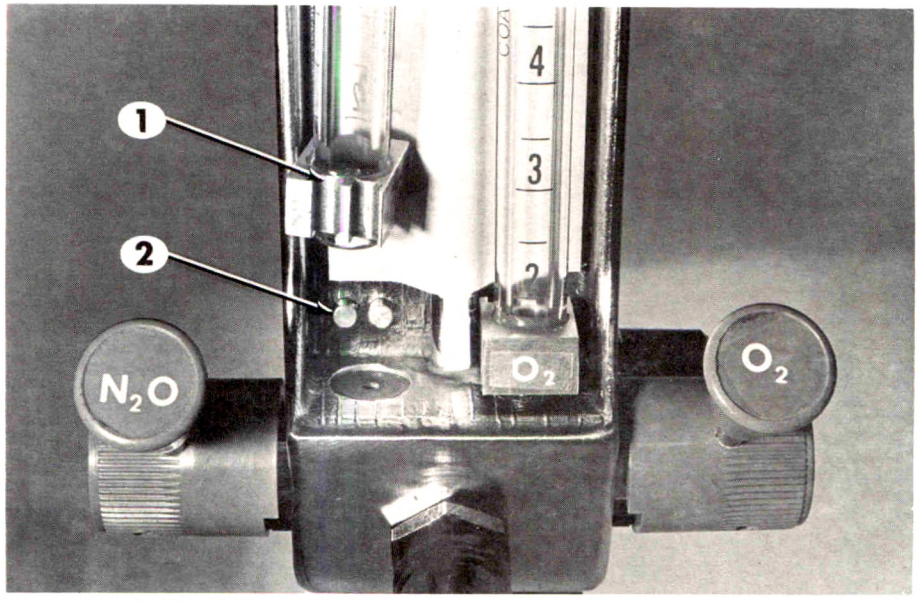

FIG 8. Prototype pin-index system for flowmeter tubes. (Developed by Porter Instrument Company, Hatfield, Pennsylvania, August 1974.) Prototype uses slots (1) machined into rear surface of metal base for flowmeter tube. When tube is correctly placed, pins (2) in flowmeter housing engage in slots and permit tube to be correctly seated. Should an error be made and an incorrect tube be placed in housing, pins do not correspond with slots and flowmeter cannot be assembled.

by using tubes with the scale and gas supplied etched onto them, or by use of a pin-index system for flowmeter tubes (fig 8). If, in addition, the balls or floats are all of the same size and weight, another chance for error is eliminated.

Touch Identification of O_2 Control Knobs.—Calverley[20] suggested and it has been agreed that the O_2 flow control knob shall have projections for positive touch identification. All the other flow control knobs will remain round (fig 9).

Prevention of Accidental Hypoxia.—The Matteo-Gissen-Lee gas-mixing system[21] and the Fraser Sweatman Quantiflex MDM System insure that not less than a preset minimum proportion of O_2 is delivered to the patient. Accidental hypoxia is thus prevented.

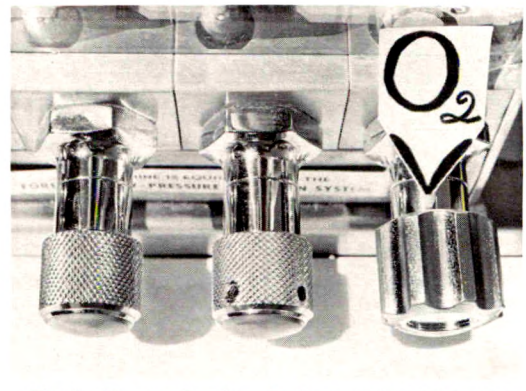

FIG 9. Proposed safety O_2 flow-control knob. Following Calverley's suggestion that the O_2 flow-control knob have projections to provide positive touch identification,[20] it is proposed that "to make the O_2 flow-control knob physically distinguishable, it shall have a characteristic profile" (shown here). "It may be arranged to project beyond the knobs controlling other gases in a bank of flowmeters. Its diameter shall be not less than the diameter of knobs controlling other gases. Other flow-control knobs shall be round." (ANSI-Z79 draft standard.)

CONCLUSIONS

There is little doubt that improvements in safety are urgently needed, but before they will be made, we anesthesiologists must indicate clearly that we will accept changes in the familiar apparatus we have used for years; the engineers would then be willing to make the changes, once they are sure other hazards are not thereby introduced. But first the firms' directors must be convinced that the disruption of the status quo is worthwhile. They will base their decisions on their sales department's report on whether their customers will welcome or at least accept the changes. Thus, in the final analysis, if enough anesthesiologists request, improvements will be introduced. Improvement awaits our initiative!

FLAIL CHEST Intermittent mandatory ventilation (IMV) combined with PEEP significantly shortened the duration of artificial ventilation in the treament of flail chest. The duration of mechanical ventilatory support averaged 18.8 days using mechanical ventilation with zero end-expiratory pressure compared with 5.1 days in patients treated with IMV and PEEP. Duration of stay in the intensive care unit correlated directly with the type of ventilatory support (23 vs 8 days). The shorter ventilation times support the thesis that flail chest is not an orthopedic problem but one of pulmonary contusion. The combination of IMV and PEEP represents an improvement in the management of patients with flail chest. *(Cullen P, Modell JH, Kirby RR et al: Treatment of flail chest. Use of intermittent mandatory ventilation and positive end-expiratory pressure. Arch Surg 110:1099-1103, 1975)*

Cardiac Failure Associated with Hypocalcemia

J. KENNETH DENLINGER, MD*
MICHAEL L. NAHRWOLD, MD*
Hershey, Pennsylvania†

Rapid transfusion of citrated whole blood was associated with acute hypotension and a rising central venous pressure in a patient undergoing pelvic exenteration and hemipelvectomy. Evidence of cardiac failure was accompanied by a precipitous decrease in serum ionized calcium (Ca^{++}) concentration. When the rate of blood transfusion was slowed, arterial blood pressure returned to the control level and serum Ca^{++} increased.

SEVERE citrate-induced hypocalcemia [serum ionized calcium (Ca^{++}) concentration <0.5 mM/L] has been reported recently in pediatric patients receiving massive blood transfusions.[1] Hypocalcemia of this magnitude produces asystole in the isolated heart preparation[2] and may result in circulatory depression in anesthetized man.[3] Previous reports have not utilized direct measurements of serum Ca^{++} activity to substantiate the diagnosis of hypocalcemic cardiac failure in anesthetized man. In the following case history, clinical evidence of cardiac decompensation was accompanied by marked, but transient, hypocalcemia.

REPORT OF A CASE

A cachectic 27-year-old woman weighing 38.5 kg was admitted to the Clinical Center of the National Institutes of Health with the diagnosis of recurrent squamous-cell carcinoma of the cervix. Extension of her disease had produced partial right ureteral obstruction; however, renal function studies were within normal limits. There was no history of cardiopulmonary disease and her chest roentgenogram and ECG were normal. With the exception of hypoalbuminemia (serum albumin = 2.7 gm/100 ml and globulin = 3.9 gm/100 ml), indices of liver function were within normal limits. Other preoperative laboratory determinations included hgb, 10.4 gm/100 ml; serum Na^+, 133 mEq/L; Cl^-, 87 mEq/L; K^+, 2.7 mEq/L; CO_2 content, 32 mEq/L; total calcium, 4.65 mg/100 ml; phosphate, 4.8 mg/100 ml. It was thought that hypochloremic, hypokalemic alkalosis was the result of gastrointestinal loss, and that adequate potassium replacement could be achieved intraoperatively.

After premedication with 8 mg of morphine and 0.5 mg of scopolamine, anesthesia was induced with 200 mg of sodium thiopental intravenously and maintained with 1 to 2 percent enflurane in N_2O-O_2. Succinylcholine (50 mg) was given to facilitate tracheal intubation, and 9 mg of pancuronium was administered in divided doses, as needed, for muscle relaxation during the 13 hours required for total pelvic exenteration and right hemipelvectomy. Direct arterial and central venous pressures (CVP) were monitored by Statham strain

FIGURE. Hemodynamic changes and serum ionized calcium measurements during rapid blood infusion.

gauge. The ECG and esophageal temperature were also monitored continuously throughout the procedure.

After 3 hours of anesthesia, the patient's arterial blood pressure remained stable at 120/80 torr, heart rate was 90 beats/min, and CVP was 2 torr (figure). Esophageal temperature had fallen to 35.1 C; arterial blood-gas analysis revealed Pao_2, 179 torr; $Paco_2$, 39 torr; and pH, 7.47. Serum Ca^{++} concentration* was 0.94 mM/L (normal range = 0.96 to 1.20 mM/L). During the following 5-hour interval, 3500 ml of warmed citrated whole blood and 40 mEq of KCl were administered intravenously. Serum K^+ increased from 2.7 to 3.2 mEq/L.

Subsequently, an abrupt increase in blood loss necessitated transfusion under pressure via two large-bore cannulas at an estimated rate of 3 ml/kg body weight/min. CVP increased from 2 to 6 torr, while arterial blood pressure decreased from 90/60 to 75/50 torr over a 5-minute period. Heart rate was unchanged at 100 beats/min during this time and normal sinus rhythm was observed continuously. Serum Ca^{++} concentration, however, decreased from 0.66 to 0.37 mM/L (figure).

With achievement of hemostasis and reduction in transfusion rate, arterial blood pressure increased to 100/60 torr and CVP decreased to 4 torr. Arterial blood gases were Pao_2, 254 torr; $Paco_2$, 40 torr; pH, 7.50, and serum electrolyte determinations were Na^+, 140 mEq/L and K^+, 2.8 mEq/L. Although no exogenous Ca was administered, serum Ca^{++} increased to 0.88 mM/L when the rate of blood transfusion was slowed.

DISCUSSION

Although the documentation of a hypotensive event accompanied by hypocalcemia does not establish a causative relationship, etiologic factors such as surgical manipulation, anesthetic overdose, cardiac arrhythmias, hypoxia, hypercarbia, and acidosis can probably be excluded in this patient. Hypovolemia must be considered as a possible cause of hypotension associated with massive blood loss; however, this patient's

*Measurement with an Orion Research flow-through Ca electrode, Model 99-20.

CVP did not decrease at any time during the rapid blood replacement. Although CVP changes observed were small, hypotension in the face of a rising CVP is suggestive of cardiac inotropic failure. Such cardiac depression may result from hypocalcemia.

The administration of citrated whole blood at 150 ml/70 kg body weight/min during a 5-minute interval to normothermic, normocarbic, and normocalcemic anesthetized man results in a 41 percent decrease in serum Ca^{++} concentration.[4] Hypocalcemia of greater magnitude, as observed in our patient, is to be expected during multiple rapid transfusions.[5,6] Hypothermia and liver dysfunction may further accentuate the degree of hypocalcemia by decreasing the rate of metabolic clearance of exogenous citrate.[6]

The spontaneous recovery to normal blood pressure with achievement of hemostasis and decrease in transfusion rate is consistent with the hypothesis that the hypocalcemia of citrate toxicity is an extremely transient phenomenon, dependent on redistribution of citrate in the extracellular fluid space, hepatic metabolism of citrate, and rapid mobilization of Ca from bone.[4] In view of the extremely rapid changes in serum Ca^{++} which occur during rapid blood transfusion, it is not surprising that a safe and effective formula for maintenance of normocalcemia does not exist.

When direct measurements of serum Ca^{++} are unavailable, ECG monitoring of the QT interval is usually recommended to detect severe hypocalcemia. Although hypocalcemia does prolong the QT interval, we were unable to detect an increase in QT duration by observation of the oscilloscopic trace. Colletti's group[7] reported that the QoTc interval may be a more sensitive index of hypocalcemia than the QT interval. The QoT interval, derived from a written recording of the ECG, is measured from the origin of the Q wave to the onset of the T wave. Correction for the effect of heart rate is made by the formula: $\text{QoTc (sec)} = \text{QoT (sec)} / \sqrt{\text{RR interval (sec)}}$.

Unexplained cardiac decompensation accompanying rapid blood transfusion is best treated by prompt achievement of hemostasis and reduction in the rate of blood administration. When this is not possible and hypocalcemia is a consideration, small doses of IV $CaCl_2$ (3 mg/kg) may be useful to restore circulatory function.[8]

Effect of Position (Semirecumbent Versus Supine) on Postoperative Oxygenation in Markedly Obese Subjects

ROBERT W. VAUGHAN, MD*
SPOMENKO BAUER, MD†
LESLIE WISE, MD‡
St. Louis, Missouri§

In 22 markedly obese, otherwise healthy, women studied postoperatively on each of days 1 through 3 after intra-abdominal operation, the effect of position change on arterial oxygenation was assessed. There was a statistically significant decrease in Pa_{O_2}, an increase in $A\text{-}aD_{O_2}$ and a simultaneous modest reduction in Pa_{CO_2} with the assumption of the supine position on postoperative days 1 and 2, but no positional difference demonstrable in any studied variable by day 3. This report suggests that during the first 48 hours after abdominal surgery in obese patients, assumption and maintenance of the semirecumbent posture is a valuable therapeutic modality to improve arterial oxygenation.

THE overall incidence of postoperative pulmonary complications, and hence hypoxemia, is affected by age, sex, duration of operation, body habitus, the existence of pre-existing pulmonary disease, and cigarette smoking.[1] Obese subjects undergoing abdominal surgery are recognized as being a particularly high-risk group in terms of postoperative pulmonary complications.[2] Recently we demonstrated that markedly obese subjects, after jejunoileal small bowel bypass, manifest significant hypoxemia during the first 4 postoperative days.[3] Since the maximum decrease in Pa_{O_2} in obese subjects occurred on postoperative days 1 or 2, any added positional effect on this already existent hypoxemia could further compromise oxygenation.

Our present study sought to identify, in a group of postoperative obese women, whether a change from the semirecumbent to the supine position would alter blood/gas exchange.

METHOD

Twenty-two morbidly obese nonsmoking women patients without clinical evidence of cardiopulmonary disease were studied postoperatively on each of days 1 through 3. Fourteen of these patients had been studied preoperatively. Informed consent was obtained from each unsedated patient preoperatively. The operative incisions (vertical midline) and surgical procedures (jejunoileal small bowel bypass, liver biopsy, and appendectomy) were identical for all patients. The overall mean duration of anesthesia was 186 minutes, with a SD of ± 23 minutes.

Samples of arterial blood were obtained

preoperatively from 14 patients and postoperatively from all subjects, breathing room air for 15 to 20 minutes. The order of sampling positions was semirecumbent, then supine, each patient serving as her own control (semirecumbent). Sampling was anaerobic, from the radial artery by direct puncture, after infiltration of the skin with 0.5 percent lidocaine, or from an indwelling intra-arterial cannula. Arterial blood was collected in iced plastic syringes containing heparin, and analyzed for Po_2, Pco_2, and pH within 30 minutes of sampling, in our research laboratory. Appropriate corrections were made for changes produced by time and temperature.[4]

The alveolar-arterial O_2 tension difference (A-aDo_2) was calculated as follows:[5]

$$A\text{-}aDo_2 = PAo_2 - Pao_2 \text{ where } PAo_2 = PIo_2 - PAco_2 \left\{ FIo_2 + \frac{1 - FIo_2}{R} \right\};$$

PAo_2 = alveolar Po_2; $Paco_2$ = arterial Pco_2; PIo_2 = inspired Po_2; R = respiratory quotient.

Since Ellison and associates[6] reported that there was no measurable change in R as a result of routine surgical operations, we have assumed that R = 0.8 throughout.

Each arterial sample was taken at least 4 hours after any narcotic medication or respiratory therapy treatments. The arterial blood samples were obtained in the semirecumbent and supine positions each morning (usually between 0800 and 1000 hr); however, beginning in the recovery area and continuing throughout the postoperative period, all patients were maintained in the semirecumbent position.

Collected data was analyzed by analysis of variance within and among the two positions studied. Subsequently, the difference in means between the control (semirecumbent) and supine positions was submitted to Student's paired *t*-test.

RESULTS

This patient sample was young (mean age 33.8 yr) and markedly obese (mean of 140% in excess of ideal weight) (table 1). In the 14 patients studied preoperatively, no statistically significant difference in any blood-gas measurement was seen in the semirecumbent versus the supine position ($p > 0.05$). Semirecumbent Pao_2 was reduced (mean 74.7 ± 1.8 torr) when compared to nonobese patients matched for age;

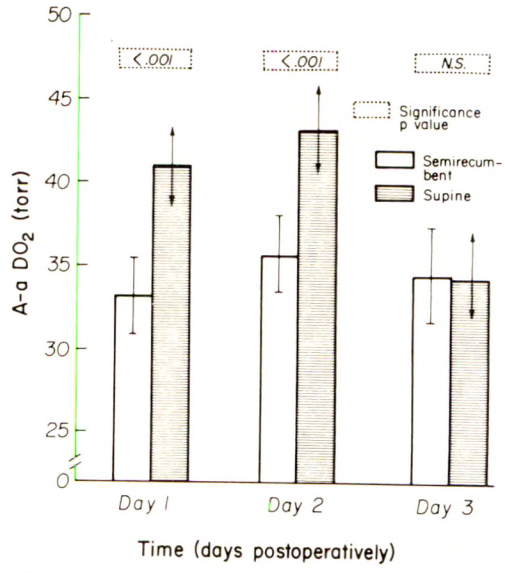

FIGURE. Alveolar-arterial O_2 tension difference (A-aDo_2) of 22 women patients in semirecumbent compared with supine position on each of postoperative days 1 through 3 (mean ± SE). On postoperative days 1 and 2, a change to supine resulted in a significantly greater increase ($p < 0.001$) in A-aDo_2. All values obtained with resting patient breathing room air.

assumption of the supine position actually improved oxygenation (78.3 ± 2.7 torr). Mean $Paco_2$ (semirecumbent) was 36.8 ± 0.6 torr, while the mean supine value was 35.1 ± 1 torr. Likewise, semirecumbent mean A-aDo_2 was 34.8 ± 1.8 torr, while supine the value decreased to 32.9 ± 2.8 torr.

Postoperatively, there was a statistically significant increase in A-aDo_2 between the semirecumbent and supine positions on postoperative days 1 and 2; no such difference was present by day 3 (table 2 and figure). Statistically significant positional differences in Pao_2 and $Paco_2$ were demonstrable on postoperative days 1 and 2 but not by the 3rd day (table 2).

No significant correlation was identifiable for the mean difference (supine-semirecumbent) in A-aDo_2 with age, weight/height ratio, or percent deviation from ideal weight on postoperative days 1 and 2.

DISCUSSION

No data are available relating the effect of changes in body position to A-aDo_2 in postoperative patients, either nonobese or obese. Since the postoperative obese patient would be at a particularly high risk if

changes in position altered gas exchange, we chose to study this group.

Tucker and Sieker[8] reported in nonobese patients the effect on lung volumes of a change from seated to recumbent position; significant decreases in all lung subdivisions except residual volume occurred. The expiratory reserve volume, in particular, was markedly reduced in the recumbent position.

Leblanc and coworkers[9] were the first to suggest the phenomenon of airway closure as a factor which might influence gas exchange with the change in posture. They pointed out that, while "closing volume" (lung volume at which airway closure started to occur) does not change substantially with posture, there is a decrease in functional residual capacity (FRC) in the supine position, thus increasing the chance of the closing volume falling within the breathing range. If this occurred, ventilation to affected regions would be impaired, thereby lowering the regional ventilation-to-perfusion ($\dot{V}a/\dot{Q}c$) ratios. This unevenness of ventilation would tend to promote arterial hypoxemia. Leblanc further reported in nonobese patients that the age at which closing volume began within the tidal range was about 65 years in the upright position and 44 years in the supine. Extrapolation of these data to our markedly obese patients is not possible.

Alexander's group[10] measured postoperative lung function to identify the mechanism of the observed hypoxemia. They demonstrated that all lung volumes were reduced following abdominal operation; the reductions were most severe after upper-abdominal operations. In their patients, there was a mean reduction of 28 percent in the FRC on postoperative day 1. They suggested that, after operation, the lung volume at which airways close [closing volume (CV)] might remain relatively unchanged while FRC decreased. Thus, there would be an increased likelihood of maldistribution of tidal volume (V_T), mismatching of ventilation with perfusion, and hypoxemia. Subsequently, they were able to show a significant correlation between the FRC-CV relationship and A-aDo_2.

Craig and colleagues[11] collected the only available data relating the effect of a change in posture (from seated to supine) on gas exchange. In 22 normal subjects, the change in A-aDo_2 with change in position as well as changes in the relationship of breathing level (FRC + V_T) to CV were evaluated. They found that the FRC decreased in the supine position, whereas CV was unchanged. The A-aDo_2 changes correlated directly

with the degree of impingement of CV on the breathing level. However, when subjects were grouped specifically according to weight, age, or smoking history, no effect of posture on gas exchange was demonstrable.

In contrast to Craig's study in nonoperated subjects, our postoperative results demonstrate that, in markedly obese women, position has a significant effect on the A-aDo_2. A possible pathophysiologic explanation for our findings is as follows:

(1) Postoperatively, abdominal muscle spasm accompanied the wound pain;

(2) Spasm of the expiratory muscles caused a rise in intrathoracic pressure leading to reduction in lung volumes, including FRC + V_T; gas exchange now took place at a lower lung volume;

(3) Subsequent assumption of the supine posture further accentuated the reduction in FRC, moving CV within the breathing range;

(4) This worsening of the $\dot{V}a/\dot{Q}c$ relationship led to a reduction in arterial oxygenation, thereby compromising overall 0_2 delivery.

It should be noted that there is another important factor in the morbidly obese. The marked weight of the abdomen can cause significant elevation of the diaphragm in the supine posture. We did not explore this factor in our study.

CONCLUSIONS

This study suggests that, in obese individuals, the assumption of the semierect posture is a valuable therapeutic modality to improve gas exchange after abdominal operation. One should be particularly cognizant of this postural effect on oxygenation in the first 48 postoperative hours. This precaution is probably most applicable to the older, markedly obese patient with a history of cigarette smoking. Prudence would dictate frequent assessment of arterial oxygenation as well as avoidance of the supine posture in these high-risk patients. Although this positional effect on postoperative oxygenation has not been demonstrated in nonobese subjects, one may suspect its occurence after thoracic and/or upper-abdominal procedures.

Hypnosis for Monitoring Intraoperative Spinal Cord Function

ALVIN H. CRAWFORD, MD*
CLYDE W. JONES, MD†
JERRY A. PERISHO, MD‡
JOHN A. HERRING, MD§
San Diego, California‖

In such procedures as the Harrington operation for idiopathic scoliosis, evaluation of spinal cord function is advisable immediately after the back is straightened. The authors have used hypnosis for this procedure, as an adjunct to anesthetic management. Patients are awakened on the table, given lower extremity tests, and are then reanesthetized. The incidence of postoperative pain and other discomfort is also reduced by hypnosis.

IN SEPTEMBER 1972, Pierre Stagnara presented a paper[1] on the advisability of checking spinal cord function during spinal surgery. As there is always a slight but real risk of paraplegia with instrumentation for correction of scoliosis, attention has been focused on the search for a method of evaluating spinal cord function during such procedures.[2,3]¶ The best and most obvious test of this function is voluntary motor power.[1]

Hypnosis.—At the Naval Regional Medical Center, San Diego, we employ Harrington instrumentation sparingly in the treatment of idiopathic scoliosis. By awakening the patient on the operating table during operation, evaluation can be accomplished much sooner than waiting until the patient is in the recovery room, over 1 hour later. We have found hypnosis useful for helping the patient cooperate in a series of intraoperative tests, moving only the desired extremities upon voice command.

¶Macewen GD: Personal communication.

Hypnosis, as described herein, is a temporary state of altered attention, induced by another person or by the subject himself, in which there is concentration upon a very narrow field. In this state, called the hypnotic trance, there is heightened suggestibility on the part of the subject, and the hypnotist can direct the subject's concentration to achieve alterations of awareness, muscular relaxation, memory, and fatigue. Sensory and motor changes can be induced and removed during this hypnotic state.[4]

The use of hypnosis in surgical anesthesia has been well established. It may be used as the sole anesthetic technic or as a supplement thereto. Posthypnotic suggestion is useful for the management of pain, muscle spasm, nausea and vomiting following operation. It can also be used to assist the patient in deep breathing and coughing following abdominal and thoracic surgical procedures.

•Untoward effects of hypnosis are a matter of controversy, but include the danger of precipitating or worsening a psychiatric illness, of masking symptoms of physical or mental disease, and of excessive dependency on the part of the patient.[5]

Hypnosis is used only as an adjunct to the anesthetic management of our patients; we do not place excessive dependence on the hypnotic aspects but regard the entire management as a unit. In conjunction with the Department of Anesthesiology, the Department of Pediatric Orthopedics set up the following protocol.

Protocol.—All patients scheduled to undergo operation for idiopathic scoliosis are admitted to the hospital 2 weeks before operation and placed in Cotrel's traction. About 1 week before operation, the anesthesiologist gives the patient a complete explanation of the reasons for the intraoperative tests, the part hypnosis plays in the total scheme, and what hypnosis is. Particular emphasis is given to explaining away the myths[6] and superstitions regarding hypnosis, stressing that the patient will also receive conventional chemical anesthesia, will feel no pain during the operation, and will probably not even recall the intraoperative awakening. A test of "hypnotizability," such as the eye-roll test,[6] is given, and in the ensuing week, the patient is placed in a hypnotic trance several times, the number of times depending on the patient's response to hypnosis and degree of cooperation.

Patients, 15 female and 3 male, ranged in age from 12 to 22, 16 being in the 12 to 16 age group, and one each ages 19 and 22. Their ages and their motivation for a successful outcome of this procedure resulted in excellent cooperation by all patients, irrespective of their degree of suggestibility. About two thirds were good to moderate hypnotic subjects. Because hynosis was not the sole technic, this was not of crucial importance.

The verbal technic was used for induction of hypnosis, achieving hypersuggestibility by a state of muscular relaxation. The onset and depth of trance were facilitated by posthypnotic suggestion and repetition of suggestions. The thrust of the suggestions during the trance state was directed at the simulation of the intraoperative scene and the tests of toe and ankle flexion and extension to be performed on command.

During the hypnotic trance, the entire procedure is outlined, with an effort to describe the situation in the operating room at the time of testing. The suggestions include that they will have no fear on the day of operation, either before, during, or after the procedure. The idea that they have control over their skeletal muscles is suggested and demonstrated. The part played by muscle relaxation in the reduction of postoperative pain is particularly stressed. It is always suggested that, while discomfort will be less, analgesics will be available if needed.

Patients are told that when they awaken, they will open their eyes and nod to show that they understand. They will not move on the table except the feet and legs, as instructed by the anesthesiologist. The reasons for their position, the function of mechanical ventilation, of the endotracheal tube, and of monitoring and IV equipment are explained. The sessions are continued one or more times a day until the hypnotist-anesthesiologist considers that results are satisfactory.

Intraoperative Management.—On the day of operation, the patient is premedicated with diazepam and a small dose of narcotic. Lactated Ringer's solution is then administered by a #14 IV cannula. Induction is with Innovar® and diazepam or sodium thiopental IV. A nondepolarizing relaxant is administered and, after spraying the larynx and trachea, the trachea is intubated by direct laryngoscopy.

Anesthesia is maintained by balanced technic, using N_2O-O_2, IV meperidine, diazepam, or thiopental and d-tubocurarine or pancuronium bromide, with controlled ventilation. By judicious use of small doses of meperidine and relaxant intermittently, reversal of these drugs is not necessary before testing.

Intraoperative monitoring includes precordial and esophageal stethoscope and temperature, ECG, and Doppler blood pressure determinations, central venous pressure, arterial blood gases, and sometimes bladder indwelling catheterization.

When instrumentation is completed, the patient is awakened by turning off the N_2O and ventilating the patient with 100 percent O_2. A 30-minute warning signal allows the anesthesiologist to "wind down" for the test. Instillation of 4 percent lidocaine by catheter into the trachea via the endotracheal tube at this time reduces the chance

of reaction to the tube, and sometimes return to spontaneous ventilation facilitates awakening. The patient blinks when awake and, understanding instructions, carries out the voluntary tests; when it is demonstrated to the surgeon's satisfaction that the cord is intact, anesthesia is resumed and the surgical procedure is completed.

RESULTS

We have now successfully monitored 18 patients using this technic and have experienced no failures. Three of the 18 patients represented the deepest trance group, as demonstrated by the induction of profound limb anesthesia, amnesia, and negative hallucination. Four staff anesthesiologists and 5 residents participated. Scoliosis has not been severe enough (39 to 109°) to require tremendous intraoperative correction, and no instrumentation has been used in any of our congenital cases.

These procedures have taken ± 5 to 6 hours of anesthesia time, the intraoperative tests being performed about 1 hour before the end. No patient has reported recall, nor has any patient manifested fear or panic during the tests. Two patients moved the arms slightly but caused no problem. No attempts have been made to induce recall of the test by hypnosis, since it is felt that this would serve no useful purpose.

Postoperative Management.—It has been noted that these patients required less pain medication in the immediate (2 to 3 days) postoperative period, but the statistical significance cannot be documented at this time and remains only a clinical impression. Postoperatively, the hypnotic trance is continued by some of the anesthesiologists to decrease immediate discomfort, bladder spasm, and nausea, as well as to teach the patient autohypnosis, a valuable adjunct to the tolerance of postinstrumentation appliances and immobilization.

CONCLUSION

It is our feeling that, far from being a mystique, hypnosis is a refined and sophisticated method of having patients move their extremities in a controlled fashion while undergoing surgical procedures and anesthesia, where indicated, instead of purposeless flailing. We plan to continue it as outlined, though not to attempt its use as the total anesthetic in this extensive surgical procedure.

METHEMOGLOBINEMIA A patient being treated for an acute myocardial infarction and receiving sodium nitroprusside to reduce left ventricular afterload developed cyanosis unrelated to hypoxia. After 4 days of sodium nitroprusside treatment (total dose 321 mg) cyanosis of the nail beds was noted and the methemoglobin level was 16%. The authors speculate that their patient had acquired methemoglobinemia, and in the absence of exposure to other oxidizing drugs or foodstuffs, that nitroprusside or one of its metabolic products was responsible for the symptoms observed. *(Bower PJ, Peterson JN: Methemoglobinemia after sodium nitroprusside therapy. The Physician & The Law

$1,237,500 Settlement for Brain Damage During Appendectomy

THREE physicians and a hospital settled a malpractice suit brought in a California trial court for a total of $1,237,500.

Claiming that the physicians and the hospital were negligent in the performance of an appendectomy on her son, the mother brought an action against them. She claimed that they failed to drain his stomach before the operation, failed to pass an endotracheal tube to assure adequacy of his air supply, and failed to monitor his heart and respiration during the operation with a precordial stethoscope.

The patient had trouble breathing on his own after surgery, and the anesthesiologist injected Prostigmin to counteract the supposed effect of curare. The patient immediately vomited and aspirated a large quantity of the material.

His heart stopped abruptly after he vomited, but he was resuscitated and left in a recovery room. The recovery room nurse was not advised that he had suffered a cardiac arrest.

He never awakened from the anesthesia and suffered seizures from permanent brain damage. At the time of trial, he was unable to speak or see and had no bowel or bladder control.

Two medical experts in anesthesiology testified that the standard of care required the use of an endotracheal tube and a precordial stethoscope. They also said that Prostigmin should not have been given without something to avoid the vomiting side-effect. One of the experts said that curare should not have been used and that blood gas tests and X-rays should have been ordered.

The anesthesiologist being sued admitted that use of an endotracheal tube was accepted practice but said that he had not

Reprinted with permission from THE CITATION published by the Law Division of the American Medical Association.

used one in order to save time. He claimed that the history of ingestion given by the patient's mother was inaccurate and was the reason for the complication.

The operating physician testified that he did not order blood gas tests because the patient's color had returned to normal just after the vomiting. The recovery room nurse testified that she made the decision to discontinue oxygen when he opened his eyes. She also decided whether to give Demerol for restlessness and when to discharge him from the recovery room.

The physician who diagnosed the patient's appendicitis and brought the operating physician into the case settled for $50,000, half to the patient and the other half to the mother to dismiss a second suit brought against him. The hospital settled before trial for $87,500.

At the start of the third week of trial the anesthesiologist settled for $1,000,000 and the operating surgeon for $100,000. The money was placed in trust, with any balance left at the patient's death to be returned to the insurance carriers for the physicians and hospital.—*Fernandez v. Salinas Valley Memorial Hospital* (Cal.Super.Ct., Monterey Co., Docket No. 69306, Oct. 28, 1974)

CORRECTION

The first paragraph under discussion in the article "Comparison of Methotrimeprazine and Meperidine as Components of Balanced Anesthesia" which appeared in the November-December issue page 754, should read:

As with other CNS depressants, the preliminary administration of MTM and meperidine significantly decreased the induction dose of thiopental. In this respect, 0.1 mg/kg of droperidol,[15] 1.5 mg/kg of meperidine, and 0.5 mg/kg of MTM are about equipotent and permit 60 percent reduction in the induction dose of thiopental.

Hemodynamic Effects of Morphine During and Early After Cardiac Operations

EMERSON A. MOFFITT, MD*
SAIT TARHAN, MD
RAMON RODRIGUEZ, MD
DONALD A. BARNHORST, MD
JAMES R. PLUTH, MD

Hemodynamics and blood gases were measured before and 15 minutes after small (10 mg/70 kg) doses of intravenously administered morphine in two groups of patients having open heart surgery. In one group, the study was undertaken after median sternotomy but before perfusion. The other group had been in the intensive care unit for approximately 1 hour. No changes were found in either group in cardiac index, atrial pressures, arterial pressure, or blood gas variables. However, mean systemic vascular resistance decreased from 41.5 to 35.4 after morphine was given postoperatively. Hence, hemodynamically, morphine is a safe drug if given in small doses for pain relief and sedation early after open heart surgery.

PREVIOUSLY we investigated the hemodynamic effects of small doses (up to 12 mg) of morphine given intravenously 1 hour after open heart operation in 32 patients.[1] With cardiac index relatively low at that time (average 2.2 liters/min per m^2), no significant changes were found in mean index, arterial and right atrial pressures, heart rate, or peripheral resistance. Because the effects were unpredictable in individual patients, we extended the study and included measurements of left atrial pressure. This paper reports the effects of morphine given intravenously (10 mg/70 kg) in 7 additional patients studied postoperatively and 10 investigated during surgery (but before perfusion).

METHODS

Sixteen of the 17 patients were men. Ages ranged from 41 to 73 years and all but one had New York Heart Association class III or IV heart disease (Table 1). Aortic valves were replaced in 11, and 6 received vein grafts for coronary artery disease. Anesthesia utilized nitrous oxide, oxygen, curare, and small concentrations of halothane. No opiates or other drugs were given, except for the morphine for the study. Perfusions employed the Bentley bubble oxygenator with flows of 2.0 to 2.2 liters/min per m^2 at temperatures of 30 to 32° C.

After induction of anesthesia, a Teflon catheter was inserted percutaneously into

the femoral artery and advanced to the thoracic aorta. Ventilation was controlled at F_{IO_2} of 0.4 to 0.5. After median sternotomy but before arterial and venous cannulations, the studies were carried out. Arterial and left and right atrial pressures and heart rate were measured and recorded, and arterial blood was sampled for blood gas determinations. Duplicate dye dilution curves were obtained utilizing transit of indocyanine green from left atrium to thoracic aorta. Then, morphine sulfate (10 mg/70 kg) was given slowly intravenously. After 15 minutes (without cardiac manipulation) all measurements were repeated. Blood gases were determined by electrodes at 37° C.

The postoperative studies were accomplished in the manner previously reported,[1] approximately 1 hour after the patients entered the intensive care unit. The sequence included sampling arterial blood, measuring and recording right and left atrial and arterial pressures and heart rate, obtaining duplicate dye curves, and then giving morphine intravenously (10 mg/70 kg). All measurements were repeated after 15 minutes. No other drugs were given before or during the study, but the chest-tube drainage was replaced volume-for-volume. Assisted respiration via endotracheal tube (F_{IO_2} 0.4 to 0.5) was employed. Mean arterial pressure was assumed to be the sum of the diastolic pressure and one-third of the pulse pressure. Systemic vascular resistance was considered to be the ratio of the difference in mean arterial and left atrial pressures to the cardiac index. The data were analyzed using Student's t test for paired and unpaired data, and each variable was compared before and 15 minutes after administration of morphine. ($P<0.05$ was selected as the level of significance.)

RESULTS

Measurements of atrial and arterial pressures, systemic resistance, and cardiac index in the intraoperative study are listed in Figure 1 and blood gases and heart rate in Figure 2. In intraoperative studies (before perfusion), no significant changes other than changes in heart rate occurred after administration of morphine.

In the patients receiving morphine postoperatively in the intensive care unit, lowered systemic vascular resistance was the only significant change ($P<0.02$) after administration of morphine (Figures 3 and 4).

Comparison of the two patient groups by analysis of unpaired data revealed mean arterial pressure and $Paco_2$ to be lower intraoperatively than postoperatively, both before and after administration of morphine. Both before and after morphine administration, mean right atrial pressure was

lower intraoperatively than postoperatively, whereas mean systemic vascular resistance before administration of morphine was lower in the intraoperative study than in the postoperative study.

COMMENT

After the appearance of the first report of the use of morphine intravenously for anesthetizing cardiac surgical patients,[2] the doses prescribed were increased to high levels (8 to 10 mg/kg).[3,4] As disadvantages became obvious,[4-7] the usual total dose prescribed was decreased to a more conservative level (1 to 2 mg/kg).[5]

Popularity of the morphine technique has prompted considerable investigation of the effects of morphine on the heart and circulation and other body systems. Stoelting and Gibbs[8] studied the effect of morphine in the most pertinent model, the cardiac patient. In their patients having aortic valve or coronary vein graft operations, a dose of 1 mg/kg significantly increased the cardiac index and lowered the systemic resistance and arterial pressure. When nitrous oxide, the agent most frequently used with morphine, was added, both cardiac index and arterial pressure decreased.

The lack of significant effect of 10 mg of morphine administered intravenously 1 hour after surgery to a 70 kg patient confirmed previous results.[1] However, this time a significant decrease in arteriolar resistance occurred. The present group of patients did have lower resistance (mean 41.5 U m^2) before the morphine was given than did those in the earlier study (mean 52.6 U m^2), but the earlier patients were severely vasoconstricted and had a lower cardiac index (mean 2.14 liters/min per m^2). Arterial and right atrial pressures and heart rates did not differ between groups. Again, we attribute the lack of effect to the small dose (compared to amounts given for anesthesia) of morphine.

Although cardiac index and left atrial pressures were the same, several differences in conditions were present between the patients studied during surgery and those studied after surgery. Arterial pressure, right atrial pressure, and systemic vascular resistance were lower intraoperatively. Lowered pressure, due to diminished vascular resistance, was likely caused by anesthesia. Another difference was the lower $Paco_2$

during anesthesia due to intentional hyperventilation. However, even on these different hemodynamics before perfusion, the small dose (10 mg) of morphine produced no significant changes.

We also measured left atrial pressure because it is a more direct determinant of cardiac output than right atrial pressure. Neither intraoperatively nor postoperatively did left atrial pressure change after administration of morphine, a finding consistent with the unchanged cardiac outputs. Therefore, hemodynamically, morphine is a safe drug if given for pain relief and sedation in small doses early after open heart surgery.

ABSTINENCE FROM SMOKING Cigarette smokers have a higher incidence of pulmonary complications postoperatively than a comparable group of nonsmokers. The authors tested the hypothesis that abstinence from smoking for a short time preoperatively was beneficial. Pulmonary function tests were performed before and for 7 days after cessation of smoking in 5 chronic smokers (mean 14 pack/day/year). All had normal spirometric measurements (FVC, FEV_1) and maximum voluntary ventilation before abstinence from smoking. In contrast, all had a significant reduction in flow at 25 per cent of the vital capacity (FEV_{25}) indicating significant small airway disease. Cessation of smoking for 7 days produced no change in any of these tests. The authors conclude that advice to "stop smoking for even 2 to 3 days before surgery" is inadequate preoperative preparation for the patient with obstructive lung disease. Chest physiotherapy, bronchodilators and breathing exercises must also be employed. *(Chodoff P, Margand PMS, Knowles CL: Short term abstinence from smoking: Its place in preoperative preparation. Crit Care Med 3:131-133, 1975)*

The Pulmonary Absorption-Excretion Volume Effect

HERBERT RACKOW, MD*
ERNEST SALANITRE, MD†
New York, New York‡

An *in-vitro* experiment demonstrated the concentration effect of N_2O (3% versus 75%) during elimination and during uptake. Other pulmonary absorption-excretion phenomena also occur simultaneously, as paired events during uptake and then during elimination: diffusion hyperoxia and diffusion anoxia; alveolar concentration of CO_2, and alveolar dilution of CO_2. These clinical phenomena, as well as the second gas effect, are all related, and the pulmonary absorption-excretion volume is found to depend in part on the type of ventilation: volume controlled, pressure controlled, or spontaneous respiration.

THE uptake or elimination of N_2O in anesthetic concentrations involves the exchange of significant volumes of this gas between lungs and blood.[1-3] Absorption or excretion of these relatively large volumes of N_2O has been associated with changes in concentrations of certain alveolar gases. These changes were reported by various investigators as different clinical phenomena, depending upon which alveolar gas was considered and whether uptake or elimination of N_2O was studied: diffusion anoxia,[2] diffusion hyperoxia,[4,5] alveolar dilution,[4] concentration effect,[6] and second gas effect.[7-9]

There is a common mechanism for each of these phenomena:[4]

1. During uptake, absorption of N_2O draws in an additional inspired tidal volume and/or reduces the alveolar volume.

2. During elimination, excretion of N_2O does the reverse, decreasing the inspired tidal volume and/or expanding the alveolar volume.

Since it is the same volume of N_2O and the same mechanism that causes all these clinical conditions, each can be regarded as a different aspect of one effect. Therefore, the phenomena must all occur together and as paired events, one due to absorption of N_2O during induction and two, its counterpart due to excretion of N_2O during recovery. Thus, diffusion anoxia (during recovery) has, as its counterpart, diffusion hyperoxia (during induction), and alveolar dilution of CO_2 (during recovery) is paired with alveolar concentration of CO_2 (during induction). The concentration effect, and its associated second gas effect, have only been reported during uptake. They should be found during recovery also.

Recently, Eger[10] stated that "recovery differs from induction by the absence of the concentration effect," basing this on two factors: uptake draws N_2O from an infinite reservoir,§ while the elimination reservoir formed by the blood is finite, and uptake shrinks the alveolar gas volume while elimination does not shrink the blood volume.

Our understanding of the basic mechanism is different: Uptake draws a finite

§Changes in tidal volume are discussed below.

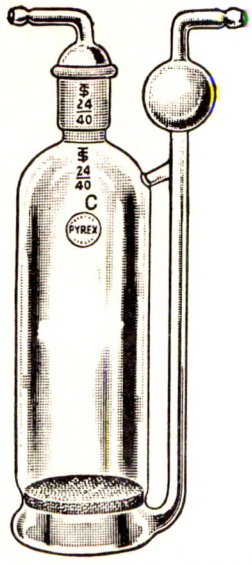

FIG 1. Gas-washing cylinder used for the "body" of equilibration studies.

volume of N_2O from an infinite reservoir, and elimination dumps this finite volume into an infinite sink. The reciprocal effects on tidal volumes and alveolar volumes have already been referred to.

In order to help resolve the disagreement, we have studied the concentration effect in a simple *in vitro* experiment during *both* uptake and elimination.

MATERIALS AND METHODS

The apparatus used for the *in-vitro* study was a gas-washing cylinder with a sintered glass disk at the bottom (fig 1).* The "body" was 600 ml of water which almost filled the cylinder, leaving a gas space of about 25 ml at the top where the standard taper 24/40 joint was located. A constant-volume Bournes pediatric ventilator or a constant-volume Harvard perfusion pump forced "breaths" of gas (100% O_2 or 3% N_2O, balance O_2, or 75% N_2O, balance O_2) through the sintered glass disk. The gas was dispersed into fine mist-like bubbles that agitated the water and emerged into the air space at the top. There the gas was sampled by a sampling pump previously described[11] and passed through an infrared N_2O analyzer.†

*B6040, Scientific Glass, Bloomfield, New Jersey.

†Beckman Instruments, LB 2 analyzer, modified by removing the linearizer. This permitted increased gain so that low and high concentrations could be analyzed without further adjustment of the instrument.

The movement of gas in the system was: tank source (100% O_2, 3% N_2O or 75% N_2O) → rubber breathing bag (fitted with a light pop off valve) → constant-volume ventilator → "body" of 600 ml H_2O → air space above H_2O → sampling pump → infrared N_2O analyzer.

The sequence in each study was:

1. 100% O_2 for 15 minutes.
2. 3% N_2O for uptake until F_E/F_I‡ reached 0.99. Ventilation continued for 15 minutes longer.
3. 100% O_2 for elimination of 3% N_2O, until a concentration of 0.05% N_2O was reached.
4. 75% N_2O for uptake until F_E/F_I reached 0.99. Ventilation continued for 15 minutes longer.
5. 100% O_2 for elimination of 75% N_2O. This constituted one study. Five studies were done.

At frequent periods during each study, inspiratory gas was sampled at the rubber breathing bag and analyzed for N_2O concentration, and the N_2O analyzer was calibrated against known N_2O concentrations delivered from previously analyzed, premixed tanks. Equilibration curves were constructed by converting "expiratory" N_2O concentrations to F_E/F_I ratios and plotting against time.

The water was kept at 0 C. The tidal volume and frequency were constant for any one study but varied among the studies from 1.5 ml to 20 ml and from 25 to 50 times per minute.

RESULTS

All 5 studies, each consisting of uptake and elimination of 3% and then 75% N_2O, showed a faster approach to equilibrium for the 75% N_2O for both uptake and elimination. In all studies, there was a greater difference between the 3% and 75% N_2O during uptake than during elimination. Figure 2 shows a representative study.

DISCUSSION

The *in-vitro* studies were designed to determine whether the concentration effect occurred for both uptake *and* elimination. There were no physiologic parameters of

‡F_E/F_I = "expiratory" concentration of N_2O/inspiratory concentration.

cardiac output or tissue perfusions, etc, that could vary and influence the results. The model consisted of 2 compartments in series: a "body" of 600 ml of water and an air space of 25 ml for sampling. The larger size of the water compartment weighted the sample to reflect predominantly the changes in the water compartment more than changes in the air space.

The N_2O absorbed from the bubbles during uptake of 3% N_2O or added to the bubbles during elimination of 3% N_2O could not have changed the bubble volume significantly. This was the control uptake-and-elimination experiment.

Absorption of 75% N_2O, however, would reduce the *size* of each bubble from that of the control (the 3% N_2O bubble), and in so doing, would increase the concentration of the N_2O (and O_2) remaining in the bubble. This in turn would increase the tension gradient and cause more N_2O to be absorbed. This is the concentration effect during uptake (and also diffusion hyperoxia) with constant volume ventilation.

During elimination, excretion of N_2O into the bubbles would increase the *size* of the bubble over that of control. This would decrease the concentration of N_2O (and O_2) in the bubble, compared to what the concentration would have been had the size remained essentially unchanged (as with 3% N_2O). This decrease in concentration would increase the tension gradient and increase further elimination of N_2O. Thus, at constant inspired volume, there should be a faster elimination as well as faster uptake, i.e., a concentration effect should occur during both recovery and induction.

It is important that both the 3% and 75% uptake studies reach equilibrium, or the same relative position from equilibrium, before the elimination studies begin; otherwise a comparison of the elimination curves is meaningless. An equal time for each uptake cannot be considered for this purpose because the 75% uptake is faster than the 3% uptake.

In all 5 *in-vitro* studies, the 75% equilibration curves approached the equilibrium limit ahead of the 3% curves for both uptake and elimination (fig 2); thus, a concentration effect is seen to exist for both induction and recovery. This lends support to our interpretation of the dual mechanisms of shrinkage and expansion which cause all

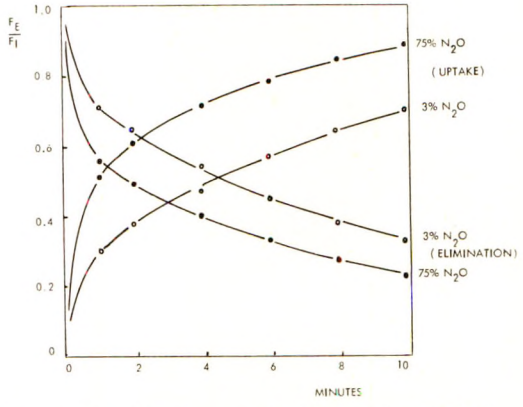

FIG 2. Equilibration of 3% N_2O and 75% N_2O during uptake and during elimination.

pulmonary absorption-excretion volume phenomena.[4]

The 3% uptake and elimination curves are virtual mirror images; this follows classic theory. However, the 75% uptake and elimination curves are *not* mirror images, the 75% uptake equilibration curve always showing a greater concentration effect than does the corresponding 75% elimination curve (fig 2). This is explained as follows:

Assume a water/air ratio of 1 and that a breath of 100 ml volume of 75% N_2O equilibrates with a 100 ml volume of water. In the first breath of uptake, 37.5 ml of N_2O should dissolve in the water, leaving 37.5 ml remaining in the air. The N_2O concentration in the water should theoretically rise to 37.5% and in the air should theoretically fall from 75% to 37.5% (75 ml of N_2O reduced to 37.5 ml/100 ml original breath volume). With the absorption volume effect reducing the total air volume, the concentration of N_2O in the air would be higher than 37.5% (37.5 ml N_2O/62.5 ml total breath volume) and the water/air ratio would not be 1. Continued absorption occurs until the ratio does become 1, at which time the concentration would be 50 ml of N_2O/100 ml H_2O and 25 ml N_2O/50 ml gas mixture (O_2 + N_2O). It is this further absorption that increases the rate of uptake for high N_2O concentrations, amounting to 12.5 ml of N_2O over and above that which would have been dissolved had no shrinkage of gas volume taken place.

After many "breaths" of 75% N_2O, at equilibrium, the 100 ml of water would contain 75 ml of N_2O. In the first breath of elimination, 37.5 ml of N_2O should theoretically enter the breath volume, leaving 37.5 ml of N_2O behind in the water. The

concentration of N_2O in the air should theoretically be 37.5% (37.5 ml N_2O/100 ml original breath volume). With the expansion effect, the volume of N_2O in the air would be 37.5 ml in a total air volume of 137.5 ml. The partition ratio would be more than 1, and further elimination would occur until the ratio reached 1. At this time, the concentration of N_2O would be approximately 31 ml of N_2O/100 ml H_2O and 44 ml of N_2O/144 ml of total air volume. This represents 6.5 ml more of N_2O than would have been excreted had no expansion of gas volume occurred. This is the concentration effect during elimination. It is less of an effect than during uptake.*

The Concentration Effect With Other Types of Ventilation.—In the present study, a volume-controlled ventilator was used and the entire effect of absorption and then excretion of N_2O was first to reduce and then to expand the bubble volume. The same effect on the alveolar volume should occur *in vivo*.

However, with a pressure-limited ventilator and with spontaneous respiration *in vivo*, other effects occur, due to changes in the tidal volume. During inspiration, absorption of N_2O draws in an equal, additional volume of inspired air. This results in a normal end-inspiratory volume of the lung and a normal end-inspiratory alveolar P_{CO_2}, despite the increased inspired volume. In effect, the increased inspired tidal volume contracts down (by absorption of N_2O) to a normal tidal volume. This increases the concentration of each gas in the *inspired* volume.

During expiration, continued absorption of N_2O reduces the alveolar volume and raises the concentration of all *alveolar gases*, O_2, CO_2, N_2O, and halothane, if present. With spontaneous respiration, the physiologic response to the increase in P_{CO_2} would be to increase (further) the next inspired breath; in effect, absorption of N_2O during both inspiration *and* expiration results in the added inspired volume. This causes a normal expired volume and a normal P_{CO_2}.

Elimination is the reverse; the excretion of N_2O during inspiration reduces the normal inspired tidal volume, dilutes the reduced inspired tidal volume, and also dilutes the alveolar volume (table).

Although the concentration effect with a volume-controlled ventilator resulted in a faster approach to equilibrium during recovery, with a pressure-controlled ventilator or with spontaneous respiration, it may result in a *slower* approach. *During uptake*, with pressure-controlled and spontaneous respiration, both the concentrating effect and the increased inspired tidal volume *speed* uptake. *During recovery*, however, although there is a diluting effect which should speed elimination, there is also a diminished inspired tidal volume which must tend to slow elimination, since it represents a form of hypoventilation.

The difference between uptake and elimination, with ventilation other than constant-volume ventilation, occurs, because during uptake, absorption *augments* the *inspired* volume and diminishes the expired volume, while during elimination, excretion *diminishes* the *inspired* volume and augments the expired volume. The alveolar-capillary tension gradient which determines the rate of absorption and excretion is a function of the inspired volume, not the expired volume. Only with a volume-controlled ventilator, is inspired volume kept constant.

Let us assume for the purposes of this discussion that with spontaneous respiration, during elimination, the inspired tidal volume is so reduced that the exhaled tidal volume and P_{CO_2} are kept constant (table). Since the expired tidal volumes are the same for elimination of both high and low concentrations of N_2O, and the inspired tidal volumes are smaller for elimination of high concentrations, there must be an overall slowing of elimination of high concentrations of N_2O compared to low concentrations. The larger the volume of excreted N_2O per breath, the greater the effect.

During recovery with a pressure-limited ventilator, just as with spontaneous respiration, there is a diluting effect, which speeds recovery, and a reduced inspired tidal volume, which slows recovery. However, the inspired tidal volume is not diminished as much as with spontaneous respiration (table), and there should be less slowing. The equilibration curve during recovery from

*An additional factor, not present *in vivo*, was that a decrease in bubble size during uptake increases the surface:volume ratio. During uptake, this may favor diffusion, if diffusion was a limiting factor under our conditions. The reverse during elimination may decrease diffusion. This may have further reduced the magnitude of the concentration effect during elimination. We thank Dr. W. Perl, New Jersey Medical School, Newark, for this suggestion.

TABLE

Effect of Type of Ventilation on Volumes Entering and Leaving Alveoli

	Inspiration			Expiration
	Volume inspired	Absorption or Elimination of N_2O		Volume expired
Control period 1,2,3. (all types of respiration)	$V_{I,c}$	None	None	$V_{E,c}$
		Concentrating Effect (absorption of N_2O_I and N_2O_E)		
Uptake period 1. Constant-volume respirator	$V_{I,c}$	$-N_2O_I$	$-N_2O_E$	$V_{E,c} - N_2O_I - N_2O_E$
2. Constant-pressure respirator	$V_{I,c} + V_{I,n2oi}$	$-N_2O_I$	$-N_2O_E$	$V_{E,c} - N_2O_E$
3. Spontaneous respiration	$V_{I,c}$ $V_{I,(n2oi + n2oe)}$	$-N_2O_I$	$-N_2O_E$	$V_{E,c}$
		Diluting Effect (elimination of N_2O_I and N_2O_E)		
Elimination period 1. Constant-volume respirator	$V_{I,c}$	$+N_2O_I$	$+N_2O_E$	$V_{E,c} + N_2O_I + N_2O_E$
2. Constant-pressure respirator	$V_{I,c} - V_{I,n2oi}$	$+N_2O_I$	$+N_2O_E$	$V_{E,c} + N_2O_E$
3. Spontaneous respiration	$V_{I,c} - V_{I,(n2oi + n2oe)}$	$+N_2O_I$	$+N_2O_E$	$V_{E,c}$

$V_{I,c}$ = control inspired tidal volume.
$V_{E,c}$ = control expired tidal volume.
$+ V_{I,n2oi}$ = additional inspired tidal volume equal to volume of N_2O absorbed during inspiration
$+ V_{I,(n2oi + n2oe)}$ = additional inspired tidal volume equal to volume of N_2O absorbed during inspiration and expiration
$- V_{I,n2oi}$ = reduced inspired tidal volume equal to volume of N_2O excreted during inspiration
$- V_{I,c\ n2oi + n2oe)}$ = reduced inspired tidal volume equal to volume of N_2O excreted during inspiration and expiration
$\pm N_2O_I$ = volume of N_2O absorbed (−) or excreted (+) during inspiration
$\pm N_2O_E$ = volume of N_2O absorbed (−) or excreted (+) during expiration

75% N_2O, using constant-pressure ventilation, should fall between that of the constant-volume ventilator and that of spontaneous respiration; but based on theory alone, we are unable to place it relative to the curve for 3% N_2O, i.e., without a volume effect.

If all parameters of uptake and elimination were held constant, the uptake equilibration curve of alveolar concentration with time would be the mirror image of the elimination curve, and independent of concentration.[12] However, because of the pulmonary absorption-excretion volume effect, ventilation is not a parameter but an additional variable. Classic theory of uptake holds only as the pulmonary absorption-excretion volume approaches zero,[6] that is, for low concentrations of soluble gases or all concentrations of relatively insoluble gases. For high concentrations of N_2O, the pulmonary absorption-excretion volume modifies the respiratory pattern of the different types of ventilation during uptake and elimination (table).

During uptake, spontaneous respiration has the largest inspired and expired volume compared to other types of ventilation; it should have the fastest rate of pulmonary equilibration and the maximum pulmonary absorption-excretion volume effects on O_2, N_2O, etc. As the constant-volume ventilator has the smallest inspired and expired volumes, it should have the slowest rate of equilibration. During elimination, the reverse occurs. As the pulmonary absorption-excretion volume approaches zero, the various modifications on all respiratory volumes, due to different types of ventilation, also approach zero.

CONCLUSIONS

The net pulmonary absorption or excretion of a relatively large volume of gas causes volume changes in the lung. This occurs during the first few minutes of uptake or elimination of N_2O in anesthetic concentrations and results in: (1) a concentrating effect during uptake and a diluting effect during elimination and, (2) changes in the inspired tidal volume, the end-inspiratory volume, the expired tidal volume and/or the end-expiratory volume. The type of ventilation, volume-controlled, pressure-controlled, or spontaneous respiration, has an effect on the pulmonary absorption-excretion volume. The clinical phenomena, diffusion anoxia, diffusion hyperoxia, the concentration effect, the second gas effect, and alveolar concentration and dilution of CO_2, are all related and all occur as simultaneous paired events during uptake and elimination with anesthetic concentrations of N_2O.

Laryngeal Stenosis in Acromegaly: A Possible Cause of Airway Difficulties Associated with Anesthesia

SHAKEELA Z. HASSAN, MD*
GREGORY J. MATZ, MD†
A. M. LAWRENCE, MD, PhD‡
PHILLIP A. COLLINS, MD§
Chicago, Illinois‖

After difficult intubation in an acromegalic patient was encountered, 7 additional acromegalic patients were studied by measuring the cricoid width and anteroposterior diameter. Cricoid width and anteroposterior diameter were generally found to be narrower than in a group of normal patients. Such narrowing may explain airway problems encountered in acromegalic surgical patients.

ACROMEGALY was first described as a disease entity by Pierre Marie[1] in 1886. Laryngeal and pharyngeal involvement in acromegaly and the clinical entity of dyspnea in association with acromegaly were first recorded in 1896 by Chappell,[2] who described a patient dying of respiratory failure. At autopsy, a note was made of marked hypertrophy of the laryngeal cartilages, thickening and enlargement of the tonsils and other soft tissues, and a very narrow opening between the vocal cords.

In 1918, Chevalier Jackson[3] reported 4 patients with acromegaly and laryngeal morbidity, one of whom required a tracheostomy for what was described as severe airway obstruction caused by overgrowth of soft tissue and cartilages. Because of this experience, Jackson advocated careful examination of the larynx in all cases of acromegaly, as serious stenosis of the larynx could lead to dyspnea and even asphyxia due to airway obstruction.

Grotting and Pemberton[4] reported that fixation of the vocal cords could be seen in acromegaly. They proposed that this was presumably due to selective growth of the tracheal cartilages, with stretching of the recurrent laryngeal nerve and subsequent cord paralysis. Siegler[5] described a 35-year-old acromegalic woman with dyspnea and inspiratory stridor, presumably caused by bilateral vocal cord paralysis. Other authors[6,7] have also reported laryngeal stenosis and airway difficulties associated with acromegaly, attributing these problems to the enlarged tongue and generally thickened tissues of the upper airway. No mention of laryngeal measurements is made in any of these reports.

Only one report[7] has attested to difficulties encountered during routine intubation

of acromegalic patients. Recently, one of us encountered difficulty during intubation of such a patient. This led us to measure 7 acromegalic patients, as determined by tomography and indirect laryngoscopy, and to compare these measurements with those of normal men and women of relatively similar age and weight.

These observations emphasize the importance of precautionary preoperative assessment of airway adequacy in acromegalic patients about to undergo surgical anesthesia. Such attention may well avoid serious morbidity during intubation, anesthesia, and recovery.

MATERIALS AND METHODS

Case Report.—A 43-year-old man weighing 88 kg was admitted for elective herniorrhaphy. Because of a mildly abnormal preoperative cardiogram, evaluation by the medical service was requested and the presumptive diagnosis (subsequently confirmed) of acromegaly was suggested. No preoperative otolaryngoscopic examination was performed. Clearance for operation was given and the following morning, 75 mg of meperidine, 10 mg of diazepam, and 0.4 mg of atropine were given as premedication at 0700 hr.

The patient was transported to the operating room where the anesthesia team started parental fluids and attached monitoring terminals. At 0815 hr, 300 mg of sodium thiopental was administered IV, followed by 80 mg of succinylcholine, and endotracheal intubation was approached using standard laryngoscopic technics. Adequate visualization of the laryngeal orifice was not difficult, yet a size 8.5 and 8 mm Murphy tubes were too large to be inserted. The patient's spontaneous respiratory effort had returned and anesthesia was continued with a face mask, using halothane-N_2O-O_2 and assisted ventilation.

On external examination, laryngeal size appeared quite large, yet the opening between the vocal cords appeared very narrow. During attempts at intubation, occasional premature ventricular contractions were encountered. Subsequently, sinus rhythm was resumed throughout the intraoperative course. No persisting ECG abnormality was seen in the postoperative period or at the time of discharge from the hospital, 4 days later.

Seven acromegalic patients, ranging from 26 to 66 years in age, were chosen for laryngoscopic studies. All had received conventional cobalt radiation therapy in the past. With two exceptions, all had had marked lowering of elevated growth hormone levels toward or into the normal range, but clinical signs of smoldering disease were considered present in all but one. Each patient underwent indirect laryngoscopic examination, with careful attention to size of the tongue, size and symmetry of laryngeal cartilages, and mobility of vocal cords. X-ray examination of the larynx consisted of frontal biplanar tomograms and routine lateral soft-tissue films. The anteroposterior diameter and width of the cricoid cartilage were measured (figs 1, 2, and 3).

RESULTS

Unfortunately, laryngeal measurements of our first-reported acromegalic surgical patient were not made. However, of the 7 additional patients, all had coarse, thickened voices and enlarged tongues. No patient had either unilateral or bilateral vocal cord paralysis. The length of the larynx appeared normal on indirect examination but the cricoid width measurements generally showed a significant narrowing when compared with nonacromegalic patients (table). The anteroposterior diameter was not narrow and conformed to data reported from normals by Maue and Dickson.[8] No apparent differerences in the thyroid cartilage or in the cricothyroid angle were noted.

DISCUSSION

Previous reports[2,4,5,9] have suggested that airway obstructive symptoms in patients with acromegaly may be due to enlarged or thickened soft tissues of the nasopharynx and larynx or associated vocal cord paralysis. Our group of 7 patients did not show strikingly thickened soft tissues of the larynx and none demonstrated recurrent laryngeal nerve palsy. However, increased hoarseness in a number of these patients could be due to some increased thickening of the vocal cords.

The tongue, although thickened in all, in itself would not appear to render intubation particularly difficult or materially lead to symptoms of dyspnea. The combination of significant decrease in the width of the cricoid arch associated with an enlarged tongue could nevertheless hamper a smooth intubation and lead to associated problems during the surgical procedure and in the postanesthetic period. Actual visualization of the vocal cords may be extraordinarily difficult.[9]

Intubation may be thwarted because of generalized thickening of laryngeal and pharyngeal structures, while anesthesia problems may arise because of the large nose, hypertrophied and obstructing nasal cartilages, prognathism and spreading teeth, and an unusually large tongue. The enlarged nose and fleshy facial soft tissues may effectively prevent adequate fitting of an anesthetic mask.

Recommendations for avoiding some of these problems[7] have included:

1. Preoperatively, the upper airway should be examined carefully, and accurate assessment made as to anticipated intra- or postoperative difficulties.

2. Intraoperatively, if difficulties in maintaining an adequate airway are anticipated, awake oral or nasal intubation under topical anesthesia or preoperative tracheostomy should be seriously considered.

3. Jackson's "sniffing" position,[10] with profound relaxation, is best for tracheal intubation.

4. Close postoperative observations of these patients will help prevent further airway complications.

THE EFFECT OF PROLONGED BREATHING OF O_2 IN HIGH CONCENTRATION ON THE RESPIRATORY SYSTEM: EXPERIMENTAL INVESTIGATIONS. Although no attempt was made to extrapolate results from dogs to man, statistically impressive data were derived from a study of 17 dogs (7.5 to 30 kg) investigated to answer 3 major questions: (1) What is the effect (in dogs) of breathing 100% O_2 at 1 atm (600 torr) for up to 48 hours? (2) Can controlled respiration alter the action of prolonged O_2 breathing in high concentrations? (3) What, if any, pulmonary damage results from breathing? Assessment of the cardiorespiratory system was based on an analysis of indices determining (1) respiratory mechanics, (2) ventilation:perfusion relationships, (3) gas-exchange values, (4) O_2 transport and utilization in tissues, (5) morphologic lung changes. The author concludes: (1) All dogs showed pulmonary damage after 30 hours, changes beginning by the 12th hour and appearing during spontaneous as well as mechanical O_2 ventilation. (2) Respiratory rate, A: a ratio, and pulmonary shunting increased; lung compliance decreased; CO_2 excretion was impaired. (3) Pulmonary morphology showed extensive atelectasis and exudative reaction. (4) Mechanical respiration increased the O_2-induced damage. (5) Long-term quiet breathing of O_2 also disturbed the $\dot{V}/\dot{Q}$ ratio. (6) If long-term high concentrations of O_2 must be administered, Pa_{O_2} should not be permitted to exceed 100 torr, as dysplasia bronchopulmonalis is likely to result even earlier in man than in dogs. *(Szreter. Anaesth Resusc Intensive Ther 1:305-324, 1973.)*

Caudal Analgesia for Quadruplet Delivery

EZZAT ABOULEISH, MD*

During the period January 1969 to November 1974, in a total of 39,800 deliveries, there were two sets of quadruplets. Both parturients had been taking ovulation-inducing drugs. Maternal problems were distended abdomen and heavy uterus, causing supine hypotension and lordosis; toxemia of pregnancy; increased possibility of hemorrhage before, during and/or after delivery; edema of the back; mental depression. The fetal problems were prematurity; intrauterine growth retardation; increased possibility of transfusion syndrome and prolapsed cord; increased obstetric manipulation.

An adequate number of obstetricians, pediatricians, anesthesiologists, and nurses, necessary equipment, and blood and blood components should be available. Early hospitalization is necessary. Close observation of the patient before, during, and after delivery is essential. The patient should stay on her side throughout labor. General anesthesia may add to fetal depression and increase the possibility of uterine atony. Spinal or lumbar epidural anesthesia may be difficult because of the associated lordosis and back edema. Caudal block allowed intrauterine manipulation, provided adequate analgesia, permitted high F_{IO_2} administration, and did not interfere with voluntary bearing down when required.

ANESTHESIA for management of patients with multifetal gestation has a vital role in the welfare of mother and neonates, yet in extensive literature on the obstetric management of four or more fetuses, anesthetic problems and management is not discussed in detail.[1-19]

At Magee-Womens Hospital from January 1, 1969 to November 30, 1974, in a total of 39,800 deliveries, two sets of quadruplets were born. Both mothers delivered their quadruplets within the last year period, and both had taken ovulation-inducing drugs. The use of such drugs increases the incidence of multifetal gestations by increasing the frequency of multiple simultaneous ovulations. In several series in which these drugs had been used thirty to 50 percent of women who conceived had multiple gestations, including quintuplets, sextuplets, and septuplets.[17] The anesthesiologist will encounter cases of multifetal gestations with increasing frequency; therefore, he should be aware of the problems involved.

CASE REPORTS

Case 1.—A 33-year-old Caucasian woman was treated for primary infertility and oligo-ovulation due to polycystic ovarian syndrome. The first fertility drug used was clomiphene citrate (Clomid®), without success. The administration of human post-menopausal gonadotropins (Pergonal®) for a 3-month period was followed by conception of quadruplets. The patient's pregnancy course was uneventful. At about 30 weeks gestation she was admitted to the hospital and arrangements were made to have adequate personnel and equipment for anesthesia, delivery, and neonatal resuscitation available at any time.

At 0800 on November 10, 1973, at 35 weeks gestation, the patient was admitted to the labor suite with irregular contractions. Her height was 170 cm and her weight at this time was 75 kg. The cervix was 2 to 3 cm dilated and the head of the first fetus was at −2 station. BP was 120/80, pulse rate was 68, temperature was

*Associate Professor of Clinical Anesthesiology, University of Pittsburgh School of Medicine; Director of Obstetric Anesthesia, Magee-Womens Hospital, Pittsburgh, Pennsylvania 15213.

36.7 C, and urinalysis was negative for albumin and dextrose. There was marked abdominal distention and lordosis but landmarks at the caudal hiatus were easily identified. She was relatively comfortable and did not require medication.

At 1530, she started to feel uncomfortable; the cervix was 8 to 9 cm dilated with the fetal head at +1 station and she was transferred to the Delivery Room, where two obstetricians, four neonatologists with necessary equipment for resuscitation and incubators, one anesthesiologist, two nurse anesthetists, and obstetric nurses were waiting. A 20-gauge Teflon epidural catheter* was inserted without difficulty into the caudal canal in the left semiprone position. To reduce the total dose of local anesthetic and to reach an adequate height of segmental block, a large segment of the epidural catheter, 12.5 cm, was left in the caudal canal to reach a high level.[20]

After a negative aspiration test for blood or cerebrospinal fluid, a test dose of 4 ml of 0.5 percent bupivacaine was injected. Five minutes later, a therapeutic dose of 19 ml of the same solution was slowly injected. The patient remained on her left side for 10 minutes, then gently turned to the other side where she remained until delivery time.

She was given 600 ml of 5 percent dextrose in water through an IV cannula within 15 minutes after the test dose, was closely monitored, and given O_2 by transparent plastic face mask. Within 20 minutes after the test dose, analgesia was adequate and extending on both sides to T-10 and vital signs remained stable. When the cervix was fully dilated, she was able to bear down while still on her side.

At 1630, the patient was transferred to the delivery table, put in lithotomy position with uterus displaced to the left, and O_2 administration was continued. Delivery of the quadruplets was uneventful and all were viable. Apgar ratings and other data are summarized in table 1. The interval between delivery of the first and last fetuses was only 19 minutes. The placentas were manually removed and the uterus was contracting well.

At 1720, the patient was transferred to the Recovery Room and the caudal catheter was removed 1 hour later. During the delivery and the postpartum period, the estimated blood loss was about 700 ml and a total of 2000 ml of 5 percent dextrose in H_2O was infused. A total of 10 units of oxytocin (Pitocin®) was infused with the IV drip. The mother's postpartum course was benign and she was discharged in 6 days.

None of the guadruplets required more than suction and O_2 by face mask and bag for about 2 minutes. However, Baby C was grunting and had transient tachypnea and retractions. O_2 was administered and his

initial blood gases on 40 percent O_2 showed a pH of 7.24, $Paco_2$ 44 torr, Pao_2 44 torr, and base excess −5. Four hours later, blood gases on room air showed pH 7.36, $Paco_2$ 40, Pao_2 48, and base excess −2. He progressed satisfactorily without need for intubation, and all quadruplets were discharged alive and well.

Case 2.—A 26-year-old Caucasian woman, 155 cm in height, gravida 2, para 1, conceived on human postmenopausal gonadotropins (Pergonal) and was closely followed as an outpatient. At 22 weeks gestation, a diagnosis of quadruplets was confirmed and she was admitted for close medical management and forestalling premature labor. Her hospitalization was uneventful except for two episodes of threatened premature labor at 28 weeks gestation and again 10 days later; both were controlled by IV alcohol administration. Because of her very distended abdomen and heavy burden, the patient was unable to care for herself during the last trimester.

On September 15, 1974, at 34 weeks gestation, the patient developed spontaneous labor. She weighed 68 kg and was markedly lordotic, with edema of back and lower limbs, BP 150/90, pulse rate 82, and a trace of proteinuria. At 2300, the cervix was 4 cm dilated and a caudal catheter was inserted in the left semiprone position. In 57 minutes, the cervix became fully dilated and she was ready for delivery. A test dose of 4 ml of 1.5 percent mepivacaine was injected through the caudal catheter, followed in 5 minutes by 15 ml of the same solution. She was then transferred to the delivery table, put in lithotomy position, uterus displaced to the left, and O_2 was administered. In 10 minutes, BP became 120/80 and analgesia level, using a pinprick, reached T_8 on the left and T_{10} on the right side.

Quadruplets were delivered in 42 minutes under adequate analgesia (table 2). Fifty-five minutes after the first dose of mepivacaine, the patient started to feel uncomfortable, and since obstetric difficulties were anticipated, the caudal block was "reactivated," using 15 ml of 0.5 percent bupivacaine.

Massive bleeding followed delivery of the fourth fetus. The uterus and cervix were intact but there were several vaginal lacerations. After 2 hours of attempting to control the bleeding with sutures, a vaginal pack was inserted and the patient was transferred to the Recovery Room. However, her condition deteriorated, a suprapubic mass was palpated and exploration under anesthesia was decided. Fifteen minutes before general anesthesia, she received 15 ml of 0.3 M sodium citrate in 20 percent syrup to raise the pH of the intragastric contents. In the operating room, 0.4 mg of atropine and 3 mg of d-tubocurarine were administered IV. Anesthesia was induced by "crash induction" using thiamylal (250 mg) followed by 100 mg of succinylcholine. Anesthesia was maintained with N_2O and O_2

(4:2), 2 ml of Innovar®, and succinylcholine drip. On removal of the vaginal pack, a hemocolpos was found. Evacuation of the hematoma revealed a spurting vaginal artery, ligation of which controlled the bleeding. The patient was then sent to the recovery room for observation. The total estimated blood loss, 2500 ml, was replaced by 7 units of blood. Urinary output was adequate. Thereafter, the patient's stay in the hospital was uneventful except for temporary mental depression. She was discharged on September 25, 1974, in good condition.

Babies B, C, and D developed mild respiratory distress syndrome at between 45, 50, and 60 minutes of age, respectively. Baby B required 24 to 30 percent O_2 with 5 percent $NaHCO_3$ for 1 day. Babies A and D developed transient hyperbilirubinemia that responded well to phototherapy. Baby D developed *E coli* sepsis, which was treated with antibiotics. All babies did well and left the hospital alive, each weighing above 2000 gm (table 2).

DISCUSSION

Many problems should be considered before choosing an anesthetic technic or drug for quadruplet delivery.

A. Maternal Problems.—Marked abdominal distention and a heavy uterus cause dyspnea and supine hypotensive syndrome; therefore, the parturient should stay on her side throughout labor, and the uterus should be displaced to the left throughout delivery. If epidural or caudal analgesia is used during labor, the patient is gently turned to the other side 10 minutes after injection of the local anesthetic, to obtain bilateral analgesia, where she stays until delivery time.

Marked lordosis due to abdominal distention makes flexion of the back and "opening" of the interlaminar spaces extremely difficult. Therefore, a midline approach for epidural or spinal is not advisable and a paramedian or lateral approach is required.

Superimposed toxemia, such as preeclampsia, is more common with multifetal gestation than in single pregnancy. Although the total blood volume in multiple gestation is higher than in single pregnancy, with toxemia complicating the former, the blood volume is less than expected.[21] Therefore, the mother with quadruplets may be hypertensive, hypovolemic, anemic, coagulopathic, edematous, and may excrete salt poorly. If toxemia occurs, certain precautions are required to avoid an excessively high block, hypovolemia should be corrected with plasma or low-salt plasma expanders rather than salt solutions, anemia should be corrected with packed red cells if required, blood coagulability should be closely followed, and blood components be readily available.

Bleeding may occur before, during, or after delivery because of premature separation of the placenta, increased obstetric interference, and/or postpartum uterine atony combined with a large placental site. Close observation of the mother, particularly in the postpartum period, is essential.

The patient is usually confined to bed during the latter part of her pregnancy. Thus, edema of the back, with or without toxemia, is not infrequent, adding to the difficulty of lumbar epidural or subarachnoid block. Therefore, the mother's back should always be examined early in labor before deciding on the anesthetic technic.

Mental depression is more common than with single pregnancy because the mother feels it will be difficult to raise four children at the same time. She is bored with the early hospitalization and suffers discomfort, dyspnea, and difficulty in moving. The obstetric team, including the anesthesiologist, should be cheerful and encouraging. Social workers and public relations personnel play an important role in supporting the mother mentally and providing means to support the family financially.

B. Fetal Problems.—Quadruplets have a high perinatal mortality and morbidity rate, and anesthesia should not be an added factor.

Because of uterine overdistention, premature labor is a major problem. Because of the limited blood supply, intrauterine growth retardation is common.[19] "Transfusion syndrome," or intrauterine "stealing," can cause problems to one fetus or more, leading to further growth retardation and anemia.[22] Contraction of the placental site or its premature separation following delivery of one or more fetuses can jeopardize the undelivered ones. These conditions make the fetuses highly susceptible to depressant drugs including anesthetics, limit their reserves, and make them easily susceptible to obstetric trauma.

Since depression secondary to general anesthesia is proportionate to the duration

and depth of anesthesia,[23] and since it takes longer to deliver four fetuses than one, general anesthesia is not the method of choice for vaginal delivery.

If the membranes are ruptured and the presenting part is not well engaged, prolapse of the umbilical cord can occur, requiring immediate interference. This problem is more frequent with multiple gestation because of the small size of the fetuses and high incidence of abnormal presentation. Adequate analgesia during parturition should therefore be available to allow for immediate intrauterine manipulation if cord prolapse occurs.

Obstetric manipulations are more common with multiple gestations than with single pregnancy, because of increased incidence of such conditions such as prolapsed cord, malpresentation, and interlocking. It is usually thought that drug-induced uterine relaxation is required for intrauterine manipulations; this is true for single pregnancy, but with multifetal gestation, uterine relaxants are not required because the uterus is usually very distended, the fetuses are usually small, and drugs such as halothane or ether add to the imminent danger of postpartum atony and hemorrhage.

To minimize obstetric manipulations, which increase maternal and fetal risks, the mother's ability to bear down should be preserved. Therefore, drugs that interfere with her state of consciousness or motor power should be avoided.

C. Anesthetic Problems.—Anesthetic agents or technic used should not reduce the already compromised uterine blood flow. Therefore hypotension, supine position without left lateral displacement, alpha--stimulants, positive-pressure ventilation,[24] and alkalosis[25] should be avoided. Adequate oxygenation of the mother, preferably allowing a high F_{IO_2}, should be considered in any anesthetic technic for the delivery of quadruplets.

Considering all these problems and requirements, epidural analgesia combined with O_2 administration, seems best for delivering quadruplets. Combined lumbar and caudal epidural (double-catheter technic) is the ideal approach where segmental lumbar epidural is used for 1st stage of labor, and both lumbar and caudal epidural for the 2nd stage. However, in our cases, the patients were relatively comfortable during the 1st stage and technical difficulty in performing lumbar epidural was anticipated secondary to marked lordosis and edema of the back.

Caudal analgesia alone in these conditions proved satisfactory and should always be considered for the delivery of quadruplets, but there are cases in which caudal analgesia is difficult or impossible, owing to anatomic variations or extreme obesity. Provided the problems and requirements of quadruplet delivery are well understood, technics other than caudal have been safely used, depending on the circumstances and the experience of the anesthesiologist and other members of the obstetric team.

General anesthesia for cesarean section using thiobarbiturate, succinylcholine, intubation, N_2O-O_2, and muscle relaxant is satisfactory.[14,16] Continuous fractional spinal analgesia was described in one case,[8] but sudden severe hypotension and respiratory insufficiency can be a problem owing to the heavy uterus and the overdistention of the abdomen. No cesarean section for quadruplets has been reported under epidural analgesia.

ACKNOWLEDGMENT

The author's gratitude extends to Mrs. Pat Sands, MPH, for revising the manuscript, and to the Misses Kathy Kutzavitch and Anna D. Francis for secretarial help.

PNEUMOPERITONEUM Pneumoperitoneum is most commonly secondary to perforation of an abdominal viscus. The authors describe two patients requiring high inflation pressures and PEEP who developed tension pneumothorax followed by pneumoperitoneum. It was speculated that air dissected through the aortic and inferior vena cava openings in the diaphragm ultimately finding its way into the peritoneal cavity. The etiology of pneumoperitoneum is difficult to determine in patients on ventilators who may be paralyzed or narcotized. The presence of a relationship between the inspiratory phase of the ventilator and accumulation of intraperitoneal air may support the diagnosis of pneumothorax and prevent an unnecessary exploratory laparotomy. *(Egan M, Boutrous A: Pneumoperitoneum following tension pneumothorax. Report of two cases. Crit Care Med 3:170-172 1975)*

We Salute . . .

Evan Lloyd Frederickson, M.D.

WHILE a bow tie, a warm smile, and a quiet "Southern drawl" are not unique in themselves, they are unique in characterizing one of the true gentlemen of our specialty, Dr. Evan L. Frederickson.

Evan was born in Spring Green, Wisconsin, and received his BS degree from the College of Agriculture at the University of Wisconsin in 1947. From 1943 to 1946, he served as a technician anesthetist for a United States Field Hospital in the Pacific. This duty influenced his return to the University of Wisconsin, from which he received his MD in 1950. Following an internship year at Walter Reed Army Hospital in Washington, DC, Dr. Frederickson migrated to Iowa City, where he completed his anesthesiology training with Dr. Stuart Cullen and acquired a Masters Degree in Science in 1953.

Between 1954 and 1965, Dr. Frederickson served twice on the anesthesiology faculty of the University of Kansas, with an interim period in Pharmacology and Anesthesiology at the University of Washington in Seattle. From 1965 to the present he has been at Emory University, where he currently is Professor of Anesthesiology, Professor of Allied Health Professions, and Professor of Pharmacology.

Dr. Frederickson is a member of 16 medical and honor societies, including Alpha Omega Alpha. He has contributed widely to the activities of the American Society of Anesthesiologists, the International Anesthesia Research Society, the Advisory Committee on Respiratory and Anesthetic Drugs of the FDA, and the Anesthesia Training Committee of the National Institutes of Health. He is a Past President of both the Kansas Anesthesiologists Society and the Greater Atlanta Society of Anesthesiologists.

Over the years, Dr. Frederickson's research interests have spanned the spectrum from chloroform to local anesthetics, as well as the current technologic advances in diagnostic procedures and biomedical research.

His ubiquitous interests, stimulating personality, and concern for improved patient care are evident throughout the 40 intradisciplinary publications bearing his name.

Although a devoted clinician and teacher, Evan makes time for weekly rounds of golf and for joining his charming wife, Ruth, in gardening. Those who have visited the Fredericksons in suburban Atlanta have seen ample reflections of this mutual interest in the meticulously "manicured" lawn and carefully pruned flowering shrubs which embellish their lovely home.

Evan and Ruth are the proud parents of three children. Mary is the oldest and has now been married for 4 years to Clinton H. Joiner, who is in the MD-PhD program at Duke University; Mary is also working on her PhD in History at the University of North Carolina. Helen, the second child, recently received her Masters degree in molecular biology in Boulder, Colorado, and was married a week after receiving her degree. She has been admitted to Emory University Medical School. Ed, the youngest, is a rising senior in chemistry and is working in the honors program in the Chemistry Department at Emory. Ed, like his father and sister, plans a career in Medicine, and will be applying for medical school this coming year.

Dr. Evan Frederickson, physician, academician, loving husband, father and friend, we salute you!

DIAZEPAM ELIMINATION The influence of age or hepatocellular disease on the disposition and elimination of diazepam was studied in man. In normal individuals, following diazepam (0.1 mg/kg intravenously or 10 mg orally) the terminal plasma half-life was age-dependent increasing linearly from about 20 hours at 20 years to nearly 90 hours at 80 years. The prolonged half-life was attributed to an increase in the initial distribution volume of the drug as diazepam plasma clearance showed no age-dependence. Therefore, despite the prolonged half-life with increasing age the constancy of plasma clearance suggests diazepam will not accumulate with chronic administration. Patients with alcoholic cirrhosis showed decreased plasma clearance of diazepam with over a two-fold increase in the drug half-life. Therefore, chronic use in these patients might result in drug accumulation. *(Klotz U, Avant GR, Hoyumpa A et al: The effects of age and liver disease on the disposition and elimination of diazepam in adult man. J Clin Invest 55:347-359, 1975)*

A Regional Anesthetic Approach for Renal Transplantation

CLARA L. LINKE, MD*
ROBERT G. MERIN, MD†
Rochester, New York‡

After consideration of surgical demands and patient condition, regional anesthesia is preferred for renal transplantation at the University of Rochester Medical Center. Of 75 consecutive cases, 64 were successfully managed with single high-dose spinal anesthesia (10 to 20 mg tetracaine, mean 16.5 mg). The technic avoids untoward effects of neuromuscular blocking drugs, iatrogenic pulmonary infection from anesthetic equipment, and problems with potent general anesthetics. Patients are made comfortable by judicious low-dose sedation. Cardiovascular instability and blood loss are not troublesome. There have been no permanent neurologic sequelae or postspinal headaches. The authors believe this technic produces minimal biochemical and physiologic derangement for renal transplantation in the patient with chronic renal failure.

THE initial report on anesthesia for renal transplantation came from the Peter Bent Brigham Hospital in 1962.[1] Dr. Leroy Vandam reasoned that, given the lower abdominal extraperitoneal surgical approach, continuous spinal anesthesia seemed a logical choice. Systemic effects of the local anesthetic was not a problem. Hypotension, in these hypertensive patients, was minimal, and neuromuscular blocking drugs were unnecessary. Tracheal intubation could also be avoided, thus lessening the risk of respiratory infection, an important consideration, since the most common complication leading to a fatal outcome in the uremic patient is infection, enhanced by immunosuppression after the transplantation.[2] There were no postspinal headaches nor neurologic sequelae in the series.

Another anesthesia pioneer in the field of transplantation, Dr. Gordon Wyant, reported his early experience from Saskatchewan.[3] Seeking advice from other anesthesiologists at the beginning of his series of renal transplants, Wyant could find no unanimity: "Because of the many contradictory statements and good reasons given for each argument by each source, we decided to develop our own initial technique based on such physiologic and pharmacologic factors as were evident or might reasonably be suspected to exist in this type of patient."[3] He also concluded that a regional technic offered the best solution.

In 1969 (in abstract form only), the group from the Peter Bent Brigham Hospital reported that they had abandoned their original concept of regional anesthesia for renal transplantation.[4] The use of routine hemodialysis produced such improvement in the clinical condition of the patient that regional anesthesia was no longer needed. The majority of anesthesiologists apparently have agreed with this viewpoint. Reported

Accepted for publication: 7/24/75

series have relied heavily on neuromuscular blocking drugs for relaxation during intravenous or inhalational techniques.[5-15]

Although hemodialysis has made a marked change in the pathophysiology of the transplant recipient, many of the early problems still are pertinent. One major concern is the lack of renal excretion of drugs. While the use of neuromuscular blocking drugs for renal transplantation is widespread, there have been appreciable problems associated with their use. Gallamine has generally been avoided in view of its predominately renal excretion.[15] Although the disposition of d-tubocurarine does not depend on renal excretion, there have been numerous reports of prolonged paralysis after transplantation.[6,9,11-13,17] Miller and coworkers[18] found that pancuronium produced a prolonged depression of twitch height in a group of anephric patients during renal transplantation, but that reversal with neostigmine was without difficulty. Concern with the use of succinylcholine has been the hyperkalemic effect of this drug. When marked hyperkalemia existed before the use of succinylcholine, significant rises were reported in serum K^+, particularly with the second dose.[19-21]

Several groups have referred to the bleeding disorders associated with chronic renal failure and dialysis. Rabiner, reviewing uremic bleeding, concluded, "It is now apparent that the major coagulation defect of uremic patients is a reversible platelet dysfunction. . . . With frequent hemo- or peritoneal dialyses the platelet abnormality can be corrected and normal hemostasis maintained."[22]

Peripheral polyneuropathy is clinically evident in many uremic patients, primarily as distal sensory and motor changes, most commonly peroneal and median nerve distributions. A generalized slowing of nerve conduction constitutes an integral part of the uremic syndrome, probably due to the inhibition of sodium transport.[23] Peripheral neurons undergo degeneration and secondary demyelination of axonal cylinders. Reversal of these changes has been documented after successful transplantation, though at varying time intervals.[23,24] Bromage observed a 38% shorter duration of local anesthesia in a report on brachial plexus block for AV fistula creation in uremic patients.[25] He attributed this to high compensatory cardiac output rather than to neuropathy. Apparently the neuropathy did not make the nerves more vulnerable to local anesthetics.

Although liver dysfunction is not an ubiquitous finding in patients with chronic renal failure on dialysis, there is an appreciable incidence of serum hepatitis.[2] The combination of hepatic and renal dysfunction may well be responsible for the problem with the disposition of various drugs in this group. Further consideration is the association of hepatic dysfunction with halogenated anesthetic agents. Although the relationship is far from clear, it seems judicious at this time to avoid repeated anesthetic procedures with these drugs.[26] Since many patients in chronic renal failure undergo repeated anesthesia, both elective and emergent,[15] the use of nonhalogenated drugs or other technics is advisable where possible.

Hemodialysis often results in effective relief of hypertension for many patients, so that the complications of hypertensive vascular disease are less frequently a problem than formerly. Unresponsive hypertension is currently one of the indications for prior bilateral nephrectomy.[15]

The biochemical disturbances produced by advanced renal failure can be fairly well controlled by effective dialysis. Nevertheless, the transplant recipient often presents with hyperkalemia and metabolic acidosis,[7] particularly if the donor kidney is from a cadaver and the timing of hemodialysis cannot be planned.

The anemia of chronic renal failure is not ameliorated by hemodialysis.[27] For an elective procedure, red blood cells can be given to the patient during the antecedent dialysis, but the recipient of a cadaver kidney is likely to present with severe anemia.

Improvement in perfusion and preservation technics for cadaver kidneys has prolonged the acceptable interval between harvest and transplantation. However, as the procedure is still considered urgent in many centers, many patients will come to operation with a full stomach. Most reporting groups have advocated "crash induction" technics.

Although the patient in chronic renal failure may be on a variety of drugs, successful hemodialysis often allows cessation of most potent medications. Some patients still need pharmacologic blood pressure control, however, so this aspect of their history must be

considered. Immunosuppressive therapy with corticosteroids, azathioprine, and/or immunoglobulin is routine at the time of transplantation.

The most commonly quoted reasons for avoiding regional anesthesia for renal transplantation have been: (1) neurologic sequelae from either abnormal bleeding at the time of the regional block or preexisting neuropathy; both have already been discussed,[22-25] (2) the psychologic state of the patient combined with the length of the procedure, and (3) instability of the cardiovascular system during regional anesthesia. These latter objections will be considered in our series of patients.

The advantages of the technic include: (1) an ideal surgical field without worry about untoward effects of neuromuscular blocking drugs, (2) avoidance of tracheal intubation, (3) relative safety in the patient with a full stomach, (4) no concern about interaction of acidosis and hyperkalemia with the anesthetic and adjuvant drugs, and (5) awake, reactive, comfortable patients in the immediate postoperative period.

Weighing all these considerations, we concluded that regional anesthesia was the most logical technic for renal transplantation. The following describes our experience with 75 consecutive renal transplantations from August 1968 to November 1974 (table).

TABLE
Renal Transplantation
University of Rochester Medical Center
75 Cases from August 1968 to December 1974

Inhalation	4	4	1	5
Neuromuscular blocking drug	3	1	0	1
Endotracheal intubation	1	1	1	3

METHODS

Preanesthetic Considerations.—At the time of the initial visit with the patient (usually soon after acceptance into the transplant program), the whole procedure was discussed and a preliminary choice of anesthetic was made. In general, patients were stable on two or three weekly hemodialyses, with reasonable blood pressure control. Thirteen patients needed antihypertensive drug therapy (11 a-methyldopa, 2 propranolol). The only other maintenance drugs were digitalis (8) and prednisone (2): 2 patients were insulin dependent diabetics. Live related transplants were scheduled on the day following routine hemodialysis during which frozen red blood cells were transfused to bring the hematocrit to about 25%. For cadaver transplants, frozen red cells were also transfused pre-operatively if hematocrit values were below 25%.

Anesthetic Protocol

1. Regional Technique.—At the beginning of the series, the surgical procedure routinely lasted longer than 4 hours. In view of this, we initially employed continuous lumbar epidural anesthesia. However, 4 of the first 5 patients required general anesthesia supplementation. A single high dose spinal was used for the 6th patient. The case proceeded so smoothly that we preferred this technique thereafter.

Tetracaine in 5% dextrose was used in a single dose. We discovered that increasing the dose prolonged the duration of the block. Thus we used 18 to 20 mg of tetracaine in a tall patient and 14 to 16 mg in shorter patients, generally women and teenagers. Epinephrine (0.2 to 0.4 mg) was added. Spinal levels of T 6-4 were sought. The early orientation of each patient was of great aid in assuring him about the regional procedure. In addition, patient-to-patient advice was often helpful. Nevertheless, since none of the operations lasted less than 2 hours, some supplementation was always

necessary. The use of small intermittent IV doses of Innovar® (total dose 2 to 5 ml) and diazepam (total dose 5 to 10 mg) produced the desired sedation while maintaining voice contact. Close observation of respiration was particularly stressed. When supplemental O_2 was needed, it was given with a disposable inhalation therapy mask. If the surgical procedure lasted over 4 hours, some patients received 50% N_2O also through the same plastic mask.

2. General Anesthesia.—General anesthesia was selected for the 3 younger children in this series and 2 adults. The need for intraoperative and postoperative assisted ventilation in one obese patient and a combined nephrectomy, splenectomy, and transplant in the other indicated the need for tracheal intubation for the adults. Light general anesthesia and continuous spinal anesthesia were employed for management of the latter case.

3. Monitoring.—The arteriovenous fistula bruit was monitored continuously to assure patency and as a cardiovascular monitor and was carefully guarded. Blood pressure monitoring has been predominately by cuff or Doppler rather than by cannulation. An electrocardiograph, preferably with a write-out capability to assess T-wave changes, was used in all cases. Central venous catheter placement through a forearm vein was successful in 56/75 cases.

4. Blood and Fluids.—5% dextrose and water was administered at approximately 0.3 ml/kg/hr using a minidrip infusion set. Blood loss was replaced as closely as possible with washed frozen red cells and albumin. Combined blood pressure, central venous pressure, and blood loss estimates guided replacement.

RESULTS

Of the 64 spinal anesthesias, 33 were managed with IV sedation alone. This comprised primarily those whose operation was completed within 4 hours. Twenty-seven others received N_2O insufflation via the plastic open-system mask. All these patients were drowsy or lightly sleeping but could be easily aroused by voice. Four patients given spinal anesthesia also received a general anesthetic (3 thiopental-N_2O and 1 halothane). As mentioned, 4/5 lumbar epidurals had to be converted to general. Of the 75 patients, 6 were intubated, and small doses of neuromuscular blocking drugs were used in only 5.

At some time during spinal anesthesia, 33/64 patients were hypotensive (greater than 25% decrease of the preanesthetic blood pressure). However, only 12/64 were hypotensive at the time of revascularization of the transplant. Of these, 3 had a systolic pressure of less than 100 torr when clamps were released. Forty-three of the 64 (67%) showed a significant rise in blood pressure within 10 minutes of revascularization; this has prompted an ongoing study of plasma renin concentrations during transplantation. No cardiac arrhythmias were observed.

Blood pressure could usually be managed by blood and albumin administration. Thirty-one patients received sympathomimetic amines, sometimes prophylactically at the time of spinal anesthesia or to restore the bruit of the AV fistula. Heparin was not used intraoperatively. More than 60% (47/75) received 1 unit or less of packed red cells and only 10 patients received more than 2 units. The largest transfusion totaled 6 units in one patient. We feel that this is an impressive argument against the supposed cardiovascular instability during regional anesthesia for renal transplantation.

The only neurologic sequela we encountered was urinary retention in one patient for 1 month which cleared spontaneously without associated neurologic findings. Several patients had significant uremic peripheral neuropathy preoperatively; the most severe had a predialysis history of footdrop which cleared after dialysis and transplantation. There were no spinal headaches or nausea. One documented pulmonary infection in the postoperative period (5 days) occurred after the combined nephrectomy-splenectomy-transplant procedure.

All patients were taken postoperatively to the renal transplant intensive care unit, where their relatively smooth immediate postoperative course was greatly appreciated by the personnel.

Patient acceptance of the technic has been most gratifying. Although, preoperatively, many patients were less than enthusiastic about the prospect of spinal anesthesia, they often remarked that the experience had been a positive one and subsequently gave positive reinforcement to prospective transplant recipients.

Spinal anesthesia did not add significantly to the morbidity or mortality in this series. Objections generally raised to spinal

anesthesia for renal transplantation (neurologic complications and cardiovascular instability) were not a problem. We believe this technic produced minimal biochemical and physiologic derangement for renal transplantation in the patient with chronic renal failure.

ACKNOWLEDGMENT

The entire dialysis and transplant team made the success of this series possible. In particular, we would like to recognize Drs. Allyn May, Richard Freeman, Charles Linke, and William A. Greene.

Rapid Anesthesia Induction in Combat Casualties with Full Stomachs

ROBERT SAMUEL CROMARTIE, III, MD*

A series of 50 combat-injured patients given crash intubation for rapid induction of anesthesia is presented. The technic consisted of injection of 3 mg of d-tubocurarine and 0.4 mg of atropine IV, preoxygenation by face mask for 3 minutes, and then injection of sodium thiopental or ketamine, followed immediately by 60 to 80 mg of succinylcholine IV. Intubation was performed with a cuffed tube after cessation of spontaneous respirations and relaxation of the jaw. In the entire series there was no vomiting or aspiration on induction. Thirty-six patients were induced with thiopental and 14 with ketamine. Three patients given thiopental and 2 given ketamine had a fall in blood pressure to below 100 torr systolic. The average BP change was in a positive direction with both agents.

INDUCTION of anesthesia in patients with full stomachs and with significant blood loss is fraught with the hazards of vomiting and aspiration as well as sudden hypotension. The present study of 50 Vietnam War casualties who required emergency surgical procedures demonstrates that the "crash" intubation technic can be reasonably safe in such patients.

METHOD

The majority of the patients were treated at the 18th Surgery Hospital in Quang Tri, Vietnam, but a few were seen in the 93rd Evacuation Hospital in Long Binh or the 91st Evacuation Hospital in Chu Lai. All were treated during the period January-October 1971. Most were operated upon within hours of receiving their wounds, through the rapid rescue evacuation achieved by the Dustoff helicopter crews.

Patients were generally taken directly to the operating room from the emergency room after rapid resuscitation with IV infusions of crystalloids and/or blood. Crossmatch facilities were not available at the 18th Surgery Hospital, so only type-specific blood was given.

Upon arrival in the operating room, the patient's vital signs were taken, he was given 3 mg of d-tubocurarine and 0.4 mg of atropine IV and was preoxygenated (100% O_2) by face mask. Three minutes after curare administration, 14 patients were given IV ketamine 2.2 mg/kg of estimated body weight and 36 received 2.2 to 3.3 mg of thiopental, followed immediately by 60 to 80 mg of succinylcholine IV. Intubation was with a cuffed tube after spontaneous respirations had ceased and the jaw was relaxed.

Positive-pressure ventilation was not generally administered until after intubation (table). At the time of intubation, the oropharynx was inspected carefully for evidence of regurgitation. Immediately after intubation, blood pressure and pulse rate were taken and the patient was then given whatever agent had been selected for use during the remainder of the procedure.

RESULTS

All 50 patients treated by this technic were successfully intubated, the oropharynx

TABLE

Technic for Rapid Induction of Anesthesia and Crash Intubation

1. Give d-tubocurarine 3 mg and atropine 0.4 mg IV
2. Preoxygenation with face mask and 100% O_2 x 3 minutes
3. Give IV ketamine 2.2 mg/kg or IV thiopental 2.2-3.3 mg/kg
4. Follow immediately with succinylcholine 60-80 mg IV
5. Wait for spontaneous respirations to stop and jaw to relax
6. Intubate with cuffed tube

in every case being free of any gastric secretions or food particles at the time of intubation. The 36 patients induced with thiopental as the principal agent required an average of 3.4 units of blood. Comparison between postinduction and preinduction BP revealed an average increase of +1.8 torr. Seven had a BP of 100 systolic or less at the initiation of induction, of whom 5 had a rise in BP, 1 had no change, and 1 had a fall from 100/80 to 90/65. Two patients with a BP greaer than 100 systolic had a fall to less than 100: in 1, from 120/70 to 80/? and in the other, from 130/80 to 90/50.

The 14 patients induced with ketamine received an average of 10.6 units of blood. They showed an average BP rise of 9 torr. Of these, 9 had a BP of 100 systolic or less at the time of induction, 4 experiencing a rise, 3 showing no change, and 2 having a fall (1 from 85/? to 75/45 and the other from 50/? to unrecordable). This last patient had received extensive injuries to liver, kidney, colon, small bowel, chest, and extremities. He survived the operation with a BP of 70/40 at the conclusion of anesthesia after 84 units of blood, but died the next day from continued hemorrhage after receiving a total of 108 units of blood. No patients given ketamine with a BP greater than 100 had a fall to below 100 systolic.

There were no intraoperative deaths in this series.

DISCUSSION

This study supports the thesis that crash intubation is an excellent technic for the prevention of vomiting and aspiration upon induction of anesthesia. This method minimizes the vulnerable interval during which the patient has lost his pharyngeal reflexes but has not yet been intubated. During the vulnerable period, should the patient vomit, aspiration would be likely.

The incidence of aspiration during anesthesia in patients who are not intubated or who are intubated with uncuffed tubes is high. Culver and associates[1] studied 300 such patients by placing Evans-blue dye in their stomachs 15 to 30 minutes before induction and inspecting the mouth, pharynx, larynx, trachea, and main bronchi with laryngoscope and by bronchoscopy at the end of the surgical procedure. Frank vomiting was noted in 8% of the patients, while the dye showed regurgitation to have occurred in 26.3% and aspiration in 16.3%.

One way to minimize regurgitation is to keep low the intragastric pressure. This pressure is greatest with the patient in a Trendelenburg position and least in reverse Trendelenburg.[2] The foot-down or head-up position has been recommended and used with good results during crash induction,[3,4] but in our study it was not used because of the risk of hypotension, since most of the patients were actively hemorrhaging at the time of induction. The head-down position affords some protection against aspiration should the patient vomit, but the incidence of vomiting is much greater and therefore the overall risk of aspiration is greater.

In the study by Culver's group[1] with the patient supine, regurgitation was found in 15.5 and aspiration in 13%, whereas in Trendelenburg, regurgitation was present in 41.4 and aspiration in 15.3%.

Succinylcholine was chosen as the paralyzing agent because of its rapid onset of action. The depolarization occurring with this drug is associated with fasciculations which may be prevented by prior infusion of a small dose of d-tubocurarine.

LaCour[5] evaluated intragastric pressures in patients given crash inductions before injection of succinylcholine and during fasciculations. He noted a mean rise in pressure of 4.6 cm H_2O, with a range of 0 to 25 cm H_2O increase. This rise was prevented by the infusion of d-tubocurarine (4 to 6 mg), 3 minutes before giving the succinylcholine. Similar results were obtained by Miller and Way.[6]

A number of reports describe cardiac arrhythmias or hyperkalemia[7-12] following succinylcholine administration. This rise in K^+ has been shown to be minimized by prior administration of d-tubocurarine.[11,13,14]

All patients were preoxygenated to help avoid hypoxia during the induction period. Forced respirations were not used before intubation for fear of forcing air into the stomach and thus increasing the risk of vomiting.

As the two anesthetic agents, thiopental and ketamine, used in this study were not randomly selected, no attempt will be made to compare the two. With both agents, the average BP change was in a positive direction.

Ketamine has been shown[15,16] to cause a rise in BP and pulse rate in normovolemic patients. Chasapakis and colleagues[17] reported similar results in 13 patients in shock, requiring an average of 1300 ml of blood and showing an average BP rise of 30 torr, with pulse rate increases of from 0 to 20 bpm.

In our series, pulse changes were not marked: average change was +4.3 bpm (range −20 to +28), the highest pulse rate being 140 (increased from 130). The BP rise in our series also was not as marked, probably due to the degree of exsanguination of the patients. Of the 2/14 patients induced with ketamine who experienced BP falls to levels below 100 systolic, both had hypotension and tachycardia prior to induction and were experiencing significant blood loss at the time of induction. (One required 8 units and the other 84 units of blood during the procedure.) Of 9 patients with an initial systolic BP of 100 or less, BP rose in 4.

Circulatory Changes During Anesthetic Induction: Impact of d-Tubocurarine Pretreatment, Thiamylal, Succinylcholine, Laryngoscopy, and Tracheal Lidocaine

ROBERT K. STOELTING, MD*
CHRISTINE PETERSON, RN†
Indianapolis, Indiana‡

Circulatory changes after IV d-tubocurarine (3 mg), thiamylal (4 mg/kg) plus succinylcholine (2 mg/kg) and followed by direct laryngoscopy with or without intratracheal lidocaine spray (2 mg/kg) just before endotracheal intubation (EI), were measured in 40 adult patients. Pretreatment with d-tubocurarine did not alter mean arterial pressure (MAP), heart rate (HR), or central venous pressure (CVP). One minute after thiamylal-succinylcholine and just before laryngoscopy, MAP was 15 torr less than the awake value ($p<0.05$) and HR was 13 beats/min greater than the awake value ($p<0.05$).

Laryngoscopy and EI elevated MAP above awake levels and further increased HR in all patients. The magnitude of these responses immediately following EI was not altered by tracheal lidocaine. However, the pressor and HR changes following EI were more transient when tracheal lidocaine was used (20 patients) and these patients were more likely to tolerate the tracheal tube without immediate additional anesthesia. The incidence of ventricular dysrhythmias was not altered by tracheal lidocaine. Compared with awake values, the cardiac index did not change significantly following intubation but stroke volume was decreased ($p<0.05$), with or without tracheal lidocaine.

RAPID production of anesthesia with an IV thiobarbiturate followed by succinylcholine and endotracheal intubation (EI) is a frequently used anesthetic induction technic. However, cardiovascular depression from the barbiturate[1] and/or a reflex sympathetic nervous system response to mechanical stimulation of the upper airway (increased BP, heart rate [HR], and dysrhythmias) during direct laryngoscopy[2-4] may occur. Nevertheless, in daily practice we rarely observed marked falls in BP after rapid thiamylal plus succinylcholine administration. Furthermore, the subsequent pressor and HR response to laryngoscopy and EI seemed transient, and ventricular dysrhythmias were infrequent. Therefore, we decided to quantitate circulatory changes occurring during a commonly used induction sequence with d-tubocurarine pretreatment, thiamylal plus succinylcholine followed by direct laryngoscopy, with or without intratracheal lidocaine spray just before EI.

METHODS

Forty normotensive adults (42 ± 6 yr, 67 ± 4 kg, mean ± SE) were studied in the supine position before elective operation. All were considered to be in ASA physical status I or II and free of organic heart disease. Each patient received intramuscular

morphine (8 to 12 mg) and atropine (0.4 mg) about 60 minutes before arrival in the operating room. A radial artery and external or internal jugular vein were cannulated, and pressures were recorded continuously as was ECG lead 2. After breathing pure O_2 via an anesthesia face mask for 3 minutes, mean arterial pressure (MAP), central venous pressure (CVP), cardiac output (indocyanine green dye and Beckman cardiodensitometer), and HR were measured. Cardiac index (CI), stroke volume index (SVI), and systemic vascular resistance (SVR) were calculated.

d-Tubocurarine (3 mg IV) was then administered. Three minutes later, thiamylal (4 mg/kg) was given IV, followed by succinylcholine (2 mg/kg). All drugs were administered rapidly as a bolus through plastic tubing leading to a 5 cm Teflon catheter (16 or 18 gauge) in a forearm vein. Flush solution (lactated Ringer's 5 ml) was injected after each drug to insure rapid entrance into the circulation. Ventilation was manually controlled via the anesthesia face mask within 15 to 30 seconds after thiamylal-succinylcholine. One minute after thiamylal-succinylcholine administration, laryngoscopy (straight laryngoscope blade) and EI were performed.

During laryngoscopy, but before placement of the endotracheal tube, 2 mg/kg of 4 percent lidocaine (LaryngoTracheal Anesthesia Kit*) was sprayed into the tracheas of 20/40 patients (group I-A). No tracheal lidocaine was used in the other 20 patients (group I-B). Following EI, the endotracheal tube cuff was inflated with air until air leak around the tube during positive pressure was just eliminated. Ventilation was then controlled with a volume ventilator delivering pure O_2 until 5 minutes after thiamylal-succinylcholine. Controlled ventilation with O_2 was continued beyond 5 minutes in 10 patients from both groups I-A and I-B until either spontaneous movement occurred or 10 minutes elapsed after thiamylal-succinylcholine administration.

*Abbott Laboratories, North Chicago, Illinois.

Data were analyzed by Student's *t*-test, $p<0.05$ being considered significant.

RESULTS

Pretreatment with d-tubocurarine (3 mg) did not alter awake MAP, HR, or CVP (table 1). Maximum MAP decreases averaged 20 torr ($p<0.05$; range 0 to 52 torr) and occurred 43 ± 2 seconds (20 to 60 sec) after administering thiamylal-succinylcholine. This produced a MAP less than 60 torr in only 2 patients. In one of these patients, MAP decreased from 69 torr awake to 44 torr, and in the other, MAP decreased from 108 torr awake to 56 torr. One minute after thiamylal-succinylcholine administration, or immediately before starting laryngoscopy, MAP was 15 torr less ($p<0.05$) than the awake value and HR was increased 13 beats/min ($p<0.05$).

Laryngoscopy and EI reversed the decreased BP and further increased HR (table 2). The average duration of laryngoscopy to accomplish EI was similar in groups I-A and I-B. Maximum MAP increases above awake levels between 1 and 2 minutes after thiamylal-succinylcholine and in association with laryngoscopy and EI were 30 torr ($p<0.05$; 0 to 84 torr) 21 seconds after completion of laryngoscopy (group I-A, tracheal lidocaine) and 37 torr ($p<0.05$; 0 to 86 torr) 15 seconds after completion of laryngoscopy (group I-B, no tracheal lidocaine). MAP a few seconds later (corresponding to 2 min after thiamylal-succinylcholine) remained similarly elevated.

†$p < 0.05$ compared with awake value.

‡$p < 0.05$. Group 1-B vs Group 1-A.

n = number of patients.

Maximum HR increases shortly after laryngoscopy and EI (for example, 2 min after thiamylal-succinylcholine) were 24 beats/min ($p<0.05$) and 28 beats/min ($p<0.05$) above awake values in groups I-A and I-B, respectively. The differences in HR and BP responses between the two groups were not statistically significant. Transient premature ventricular contractions (PVCs) occurred in 3 patients (group I-A, 2 patients; group I-B, 1 patient) during or within 1 to 2 minutes following laryngoscopy and EI. Three minutes after thiamylal-succinylcholine, SVI was significantly decreased in both groups but the elevated HR maintained the CI slightly above awake levels. CVP increased a like amount ($p<0.05$) in both groups and corresponded to the initiation of positive-pressure ventilation 15 to 30 seconds after thiamylal-succinylcholine.

Five minutes after thiamylal-succinylcholine, the MAP and HR had returned toward awake values in those receiving tracheal lidocaine (table 2). In contrast, 5 minutes after thiamylal-succinylcholine administration to patients not receiving tracheal lidocaine, the MAP and HR remained significantly greater than awake values and the corresponding measurements in those receiving tracheal lidocaine. Ten patients not receiving tracheal lidocaine during laryngoscopy were reacting to the endotracheal tube between 5 and 8 minutes after thiamylal-succinylcholine. In contrast, 4/10 patients given tracheal lidocaine during laryngoscopy reacted spontaneously to the endotracheal tube 9 to 10 minutes after thiamylal-succinylcholine. The remaining 6 patients did not move despite the turning of their heads 45 degrees to the left and right 10 minutes after thiamylal-succinylcholine. Ulnar nerve stimulation (Peripheral Nerve Stimulator, 50 Hz) revealed some residual neuromuscular blockade in those patients not moving after 10 minutes.

DISCUSSION

A small dose of d-tubocurarine before anesthetic induction did not alter MAP or HR. Subsequent rapid IV administration of thiamylal (4 mg/kg) and succinylcholine (2 mg/kg) was associated with significantly lowered MAP and increased HR. However, the magnitude of these changes was usually clinically insignificant. For example, 1 minute after thiamylal-succinylcholine, the MAP was decreased 15 percent from awake values (98 to 83 torr) and HR increased 18 percent (75 to 88 beats/min). MAP decreased below 60 torr in only 2/40 patients.

Laryngoscopy and EI reversed the BP decrease and further elevated HR above awake levels in every patient. The magnitude of these responses immediately after intubation was not altered by intratracheal lidocaine spray just before placement of the tube in the trachea. This lack of influence of tracheal lidocaine was predictable, since the tracheal mucosa would not yet have been anesthetized. Furthermore, Takeshima's group[5] considered direct laryngoscopy and not EI as responsible for such circulatory responses. Nevertheless, Denlinger and coworkers[6] demonstrated that tracheal lidocaine 5 minutes before a second laryngoscopy and EI attenuated the BP and HR responses.

Systemic absorption after tracheal lidocaine spray (2 mg/kg) has been found to result in plasma arterial lidocaine levels less than 2 mcg/ml[7] during the period of our study (for example, the first 9 min after tracheal lidocaine). This concentration is below the level associated with direct myocardial depression[8] or that effective in the treatment of ventricular irritability.[9] Therefore, direct myocardial depression in our patients receiving tracheal lidocaine seems unlikely. Likewise, an antiarrhythmic effect was not documented, as PVCs after intubation were rare and short-lasting, with or without tracheal lidocaine.

Other efforts to prevent the circulatory responses to laryngoscopy have not been entirely successful or practical. For example, deep anesthesia reduced cardiovascular changes during laryngoscopy in one study,[3] but in another report 30 minutes of prior halothane did not change BP responses from those seen in patients intubated after thiopental plus succinylcholine.[10] Topical anesthesia did not abolish circulatory responses to EI[4] and in some instances the topical procedure itself produced significant BP changes.[11]

Only DeVault and associates[12] prevented HR and BP responses by administering phentolamine before laryngoscopy. It would seem reasonable to conclude that the transient circulatory responses to direct laryngoscopy and EI are probably innocuous in normotensive patients. Overzealous use of deep anesthesia, topical anesthesia, or depressant drugs, in an attempt to prevent changes caused by laryngoscopy and EI,

may ultimately introduce more hazard than the response it was intended to attenuate.[13]

The HR increase following thiamylal-succinylcholine, but before laryngoscopy, may represent a baroreceptor response to decreased MAP or a specific effect (possible sympathetic postganglionic stimulation)[14] of succinylcholine. The increased HR associated with succinylcholine administration and direct laryngoscopy may attenuate decreased cardiac output normally resulting from thiobarbiturate-produced reductions in the SVI. Indeed, CI following intubation was maintained near awake levels in the presence of an increased HR and decreased SVI.

We conclude that the anesthesia induction sequence described in this report did not produce excessive BP decreases in normotensive and normovolemic adults. The subsequent pressor and increased HR response to laryngoscopy and EI were transient, and ventricular dysrhythmias were infrequent. The duration, but not the magnitude, of the BP and HR responses was even further shortened by tracheal lidocaine at the time of intubation. Tracheal lidocaine also prolonged the period most patients tolerated the endotracheal tube without moving when additional anesthesia was not provided immediately after intubation.

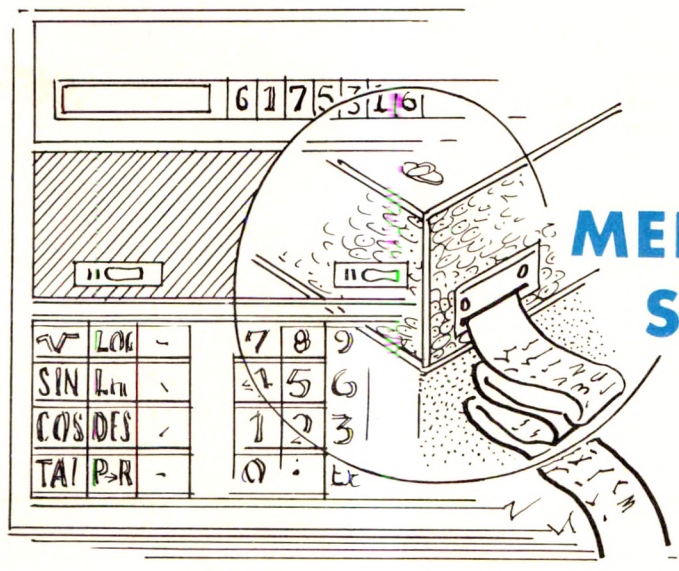
PREVENTION OF CROSS-INFECTION BY GRAM-NEGATIVE BACTERIA (German). The increased use of mechanical appliances and aerosols has created favorable conditions for a rise in nosocomial infections, many of which could be avoided by proper aseptic technics. Tracheotomized patients are particularly at risk. Exhaustive study of recent world literature shows nebulizers to be the most frequently involved and to harbor the widest variety of organisms and pneumonia to lead the list of diseases contracted. The limits of efficacy in various disinfection and sterilization methods are described as a contributory factor in epidemics of cross-infections. *(Werner. Prakt Anäesth 9:316-330, 1974.)*



MEDICAL STATISTICS

Statistical Pearls. I. An Empty Shell Game

PATRICK D. HARRIS, PhD*

THE medical researcher, with a faithful student on his side, knelt at one end of a long hallway and carefully unrolled 30 meters of 8-channel polygraph paper on the floor. After a half-stooped but brisk walk alongside the "results" of the latest 4-hour experiment on blood flow in the pump-perfused dog, the perspiring investigator declared that there wasn't a single "typical response" in the whole record. The student suggested a calculation of a "mean response;" however, their array of old and dusty hardbacks on statistics did not treat the realities of intermittent sample times, unsynchronized measurements of several variables, shortened protocols, baseline drift, ruined blood samples, unanticipated hemorrhage sites, to name but a few.

Reluctantly, they made the much-dreaded trip to the classical statistician, which yielded the oft-heard, "You can't do that." "What kind of distribution do you have?" "We could try this if . . ." and "Why don't you repeat the study?" It is no wonder that a medical researcher, with his everyday, anything-but-standard data, feels like the carnival-goer who has just picked the empty shell for the tenth straight time.

At the gracious invitation of the Editors of *Anesthesia and Analgesia*, I have planned a series of articles to attempt to provide "statistical pearls" for many of the shells of data that realistic medical research gives to all of us. This series will treat several of the common statistical procedures with heavy doses of "intuitive feel" rather than rigorous derivations. I personally believe (or should I say that I am 95% confident) that much of the data from medical research does not meet the precise, theoretically-based requirements for a cookbook application of typical statistical procedures. (This

*Investigator, Dalton Research Center; Associate Professor of Physiology, University of Missouri School of Medicine, Columbia, Missouri 65201.

is especially true for the parametric tests which are the most commonly used procedures.)

How can the researcher decide whether or not it is appropriate to apply a specific statistical test for data which have already been collected? How much data (determinations, patients, animals, experimental groups, etc) are needed for a valid application of a certain statistical procedure? If the data do not quite fit a cookbook example, is there any statistical test that can be applied? Is there a special treatment for the one extreme data point in a large series of measurements? These, and many others, are questions which constantly arise for all, experienced and beginner, who are involved in the day-to-day collection of experimental data.

It is my intent to suggest practical approaches which will provide reasonable answers to these questions. What is reasonable? One approach is to be conservative. Suppose that I am not sure that my data meet the theoretic requirements for the application of a specific statistical test. In this case, I might use a less rigorous approach which is coupled with a "less than normal" chance (more stringent criterion) for accepting a statistically significant difference. This allows an individual to be comfortable that he has a real observation when he obtains a statistical difference even though his data do not fit a standard approach.

The foregoing description of "conservative" brings to mind the problem of defining statistical terms for the nonstatistician. This is a problem, because there are widely varying definitions even for such basic terms as statistics and statistical methods. Regardless of differences in precise definitions, there are two major divisions of statistics, descriptive and inferential.[1] Descriptive statistics are a mechanism for conveniently *describing* a large set of measurements, for *relating* one measurement to another, and for *exploring* general characteristics of the data. Typically, this form of statistics does not employ *t*-tests or levels of probability. In fact, one hardly even encounters the concept of a population versus a sample. Descriptive statistics do not provide a statistical answer to a scientific question; however, they can lead an individual to a question that can be answered.

Inferential statistics are a mechanism for *interpreting* several sets of measurements to reach a conclusion about a phenomenon, for *inferring* characteristics about unmeasured data, and for *directing* the course of additional measurements. This form of statistics requires the statement of a scientific question to be answered (a hypothesis to be refuted or accepted). To be more specific, inferential statistics involve the use of a limited number (sample) of people (or animals, excised organs, cell cultures, etc) to obtain a "good" estimate of the answer to a SPECIFIC QUESTION about the characteristics of a much larger number (population) of people, etc.

Success in the use of inferential statistics depends on the definition of the *population* and the *specific question* which then, and only then, defines an appropriate sample. In many situations, a "general" population will be defined by an experimental condition, eg, hemorrhagic hypotension, or a clinical procedure, eg, small-bowel resection, or a disease entity, eg, spongedivers disease (not exactly common in rural inland areas but nevertheless a very interesting population).

The "specific" population is defined by the specific question to be answered. Is there a difference between halothane and cyclopropane anesthesia with regard to the level of renal function during the first 6 hours following operation on the hemorrhagic hypotensive patient? For this specific question, the appropriate population does not include any past, current, or future patients who receive an anesthetic other than halothane or cyclopropane. The specific population does include all patients with hemorrhagic hypotension who undergo operation, regardless of the etiology of the hemorrhage or the type of surgical procedure. This specific population certainly includes all ages, both sexes, and remarkable as well as unremarkable medical histories.

The most important point is that a general population and a specific question enable the researcher to make a list of the characteristics, both general and detailed, which describe the specific population. Why make a list? This is the most effective way to answer, "Wait a minute, I'm really not interested in *that* population." This usually will lead to the choice of a more appropriate question for the population that really is of interest to the investigator.

Much of the time, inappropriate statistics surface in scientific publications in one of

three ways. First, purely descriptive statistics are used for major inferential purposes. Second, inappropriate inferential statistics are used because one has not stated a question to be answered. Third, raw data or minimally processed data are reported, when descriptive statistics would lead both the author and the reader to an important question which should be investigated by inferential statistics.

We all know that, many times, data are collected long before one thinks about the population, the question, or the characteristics of an adequate sample. Although this is not a desirable approach for inferential statistics, it does happen for many valid reasons. A patient "of interest" presents himself on short notice; one may not know how often a specific measurement can be made; an individual may not be sure that there will be anything of interest in the initial measurements. Data collected under these circumstances are a prime candidate for descriptive statistics in order to "discover" a question. Such a discovery leads to: "I thought that the shell of data was empty, but there really was a pearl of knowledge within."

DEFIBRILLATION THRESHOLD The authors studied the influence of acid-base derangements on the external defibrillation threshold in dogs. Dogs were divided into 5 groups according to their acid-base state-respiratory acidosis, respiratory alkalosis, metabolic acidosis, hypoxia and control. Ventricular fibrillation was electrically produced and 90 seconds later the amount of energy necessary for electrical conversion was determined. Successful external defibrillation was possible in 75 per cent of all animals with 4 joules/kg or less. Thus, regardless of the acid-base status or arterial oxygenation prior to fibrillation, high energy levels were not necessary to achieve electrical conversion in most animals. However, the presence of metabolic acidosis and hypoxia impaired resumption of effective circulation following successful defibrillation. Hypercarbic animals had a high incidence of return suggesting that this derangement was not as detrimental to circulatory dynamics after electrical conversion. *(Yakaitis RW, Thomas JD, Mahaffey JE: Influence of pH and hypoxia on the success of defibrillation. Crit Care Med 3:139-142, 1975)*

Cardiovascular Effects of Enflurane and Halothane on the Rhesus Monkey

JOHN R. RITZMAN, Major, USA (MC)*
HOWARD H. ERICKSON, Lt Col, USAF (VC)†
EDWARD D. MILLER, JR, Major, USA (MC)‡
Fort Sam Houston, Texas

Ten rhesus monkeys were chronically instrumented to compare the cardiovascular effects of enflurane and halothane. In 17 experiments, each monkey was evaluated in the awake state and after equilibration at each of many anesthetic levels. End-expired gas concentrations were expressed in multiples of human minimum alveolar concentrations (MAC) for comparison.

There was a predictable dose-related decrease in heart rate, mean arterial pressure, peak left ventricular dp/dt, and the latter divided by left ventricular developed pressure $\left(\frac{dp/dt}{LVDP}\right)$ with both agents. Central venous pressure was increased by both. At equal MAC levels, no significant differences were detected between halothane and enflurane. Cardiac output and aortic flow acceleration were obtained on one of the animals for both agents. Results were consistent with those for the other measured parameters.

SINCE the appearance of enflurane as a new halogenated anesthetic agent, little agreement has been reached as to its effect on the cardiovascular system, and in particular, on the left ventricle. Both *in vitro* and *in vivo* studies (some unpublished) have produced conflicting results.[1-7] Some conflicts are explainable by differences in anesthetic concentration, experimental models, and choice of contractility index; others, however, involve very similar conditions employed by different groups of investigators.

In considering the use of enflurane for cardiac patients, it was concluded that more needed to be known about its effects on the healthy heart. The present study was designed to evaluate the effects of enflurane on the left ventricle in the intact nonhuman primate because of its similarity to man. Each primate was chronically instrumented to measure left ventricular pressure, aortic flow, and other parameters. Control recordings were obtained in the awake, unmedicated state; anesthesia was not complicated by the use of other drugs. Each

This study was supported in part by NASA Contract A-94544.

The animals involved in this study were procured, maintained, and used in accordance with the Animal Welfare Act of 1970 and the "Guide for the Care and Use of Laboratory Animals" prepared by the Institute of Laboratory Animal Resources—National Research Council.

Paper received: 6/20/75
Accepted for publication: 8/9/75

animal could be exposed to enflurane and to halothane, the latter being selected as the standard for comparison because of its wide use and well-known cardiovascular effects.

METHODS

Two weeks prior to experimentation, 10 healthy rhesus monkeys (3 to 4.2 kg) (Macaca mulatta) were instrumented through a left thoracotomy. They were premedicated subcutaneously with 0.04 mg/kg of atropine. Anesthesia was induced IV with thiopental sodium (35 mg/kg) and was maintained with a mixture of halothane-N_2O-O_2. Dosages of thiopental and atropine were consistent with current practice for experimental animal surgery.[8]

A Doppler ultrasonic flow probe was placed around the ascending aorta, a high-fidelity pressure transducer (Konigsberg Instruments, Pasadena, California) was implanted in the left ventricle, and ECG wires were sutured onto the epicardium. All leads were brought subcutaneously into a plastic photographic film container. In one end of the container, a 7-prong socket was mounted for the flow probe and ECG leads. Inside was sufficient room to house the pressure transducer plug and fluid-filled catheters when not in use. The container was cemented to a previously mounted skull pedestal similar to that described by Wolfe.[9]

Recovery required from 7 to 10 days, during which the animals received a regular monkey diet. One to 3 days prior to study, the monkeys were again anesthetized and heparin-filled central venous and carotid arterial catheters were inserted and exteriorized subcutaneously into the container.

On the morning of the experiment, the monkeys were restrained supine in a chair with which they had previously been familiarized. They were neither fasted nor medicated. After control recordings, anesthesia was induced by mask, using a Jackson-Rees apparatus. The trachea was intubated and the animal ventilated with an anesthetic-O_2 vapor at 15 ml/kg. The rate was adjusted to maintain the end-expired CO_2 between 4 and 5%, monitored with a Beckman LB-1 infrared analyzer.

The animals were maintained at an initial inspired concentration for 1 hour before recording, and at each subsequent concentration for 0.5 hour. At least 48 hours elapsed between exposures. Monkeys were alternated in the order in which they received the 2 agents, and also in the order of concentrations (light to deep versus deep to light in 0.25 MAC increments). In 5 experiments, the anesthetic sequence was repeated following beta-adrenergic blockade with IV propranolol (1 mg/kg). Our dosage of propranolol was based on the amount we have determined necessary to block a cardiac-rate response to isoproterenol (1 μg/kg). Up to 2 mg/kg of propranolol has been found to have little effect on the performance of the intact greyhound.[10]

Anesthetic levels were determined by gas-chromatographic analysis of end-expired samples and expressed in multiples of human MAC.[11,12] Standards were made after the method of Dobkin.[13] Data were recorded on analog magnetic tape and converted to digital form at 250 samples per second. The results of 10 consecutive cardiac cycles were averaged for each determination.

RESULTS

Data were compared in two different ways. First selected for analysis were those experiments for which recordings at control, near 1 MAC (light), and near 1.5 MAC (deep) were obtained. This involved 10 monkeys and included 6 exposures to halothane and 11 exposures to enflurane. Each variable for each agent was analyzed, using a 2-way analysis of variance, assuming no association between data collected on the same animal on different days.

All means and statistical results for these variables (table 1) show definite dose-related changes with either agent. For any of the variables measured, there was no significant difference between enflurane and halothane at control or at either MAC level. Comparisons between agents are unpaired.

Next, all available data were used to examine the linear relationship of each variable with MAC. The least-squares procedure was used to regress the dependent variable, "y," (for example, heart rate) on MAC values. The equation obtained was of the form $y = a + b\,(MAC)$, where a is the intercept and b is the slope. In the equations for heart rate (HR), maximum dp/dt, and mean arterial pressure (MAP) regressed on MAC (fig 1-3), the regression lines do not significantly differ between the two agents for any variable ($p < 0.05$). Equations and statistical information are shown in table 2.

For both agents, when a monkey received more than 1 exposure to an agent, data were

treated as though from a different animal. This appeared to be justified from an inspection of the results.

Data were obtained from aortic flow measurements for only 1 animal at different MAC levels. Such flow-probe failures as occurred were in most instances the result of leakage of body fluids into the probes, leading to shorted circuits, and were caused by technologic maladroitness. These data and derived variables presented in table 3 substantiate the other findings reported in table 1.

DISCUSSION

Myocardial effects of enflurane have been studied in a variety of ways. Two groups of investigators used isolated cat papillary-muscle preparations. Brown and Crout[1]

TABLE 2

Regression Equations (see fig 1-3)

Anesthetic agent	Equation	Number of data pairs used	Standard error*	r†
Halothane	MAP = 97.99 - 41.22 MAC	35	13.80	—0.90

found enflurane to be the most depressant of 5 general anesthetic agents. Shimosato's group[2] reported enflurane to be less depressant than halothane or methoxyflurane. When Shimosato's results are expressed in MAC as suggested by Saidman,[3] enflurane still remains less depressant than halothane.

In dogs, Shimosato[4] reported a shift to the left of the force velocity curve and a decrease in max dp/dt with enflurane, thus indicating negative inotropy. Tarnow[5] reported significantly decreased MAP, cardiac output, stroke volume, and max dp/dt with both halothane and enflurane, and concluded that the latter offers no cardiovascular advantage over halothane.

Etsten* reported that enflurane did not affect human right ventricular V_{max} or cardiac output. Dobkin[6] and Graves and Downs* found decreased cardiac output in humans under enflurane. Conversely, Rouge* reported increases in cardiac output with increasing depth of enflurane, attributing this to catecholamine release in response to a markedly elevated $Paco_2$.

Many indices[14,15] have been proposed to assess myocardial function, including max dp/dt, dp/dt/IP, and maximum aortic flow acceleration. Of these, nearly all are affected significantly by changes in preload, afterload, HR, and systemic resistance (SR). Reportedly unaffected is maximum intrinsic velocity (V_{max}).[16] This can be obtained from a left ventricular (LV) pressure tracing and its first derivative, dp/dt. However, we were unable to obtain consistently reliable V_{max} computations from these data, due at least in part to rapid heart rate.

Therefore, max dp/dt, dp/dt/LVDP and, where available, aortic flow data are reported. The awake monkey was its own control. Each was exposed to different anesthetics on different days under identical conditions. Changes in MAP, CVP, HR, and SR were the same for enflurane and halothane. This suggests that the major variables which may influence contractile measurements were similarly affected by both drugs. Therefore, the reported parameters should be valid indicators to compare effects of anesthetics on myocardial contractility. Although the data in table 3 suggest that cardiac output decreases with enflurane, additional experiments are needed to confirm these findings.

We gained the clinical impression that these nonhuman primates behave much the same as humans under these two clinically somewhat different anesthetics. The only notable exception is HR, which was decreased during anesthesia in these excitable small animals. Most investigators report an increasing HR with increasing depth of enflurane in humans. In the majority of

*Unpublished data to Ohio Medical Products.

human studies, however, the patient received a narcotic or barbiturate and an anticholinergic premedication. It is therefore difficult to say if a monkey's HR responds differently to enflurane than that of a human.

In 2 instances for halothane and 3 for enflurane, the anesthetic sequence was repeated following beta blockade with propranolol. Propranolol decreased max dp/dt by approximately 50% in the awake, conscious monkey. But while anesthetized by either agent, no appreciable change in dp/dt was brought about by the addition of propranolol. While there is insufficient data to justify a conclusion, one might speculate that both agents affect dp/dt by interfering with the sympathetic nervous system and specifically the beta-adrenergic response.

Guest Discussion

EVAN L. FREDERICKSON, MD
Anesthesia Research
Emory University
Atlanta, Georgia

Many writers have tried to describe the different effects of various interactions of anesthetic agents and the cardiovascular system. Each has presented data from a slightly different preparation, and conditions or concentrations have varied. As a result, arguments continue to flourish, with various individuals coming to different opinions via the work of the individual that happens to fit his own prejudices.

The very sophisticated study by Dr. Ritzman, using a primate preparation, concludes that there is little difference between the action of these two agents on the cardiovascular system. Dr. Ritzman, I believe, should be congratulated on coming to this conclusion, as it is probably closer to the truth than many of the differences that have been poorly defined in other studies.

However, there are some problems with his preparation that were not too well described. In spite of the fact that this is a primate, it obviously was a very frightened postoperative primate in the control period, with a heart rate of 185 to 200 at this particular time. Also, blood pressure was probably increased beyond normal with the mean pressure approximately 100 and over in each of the groups. The animals were obviously in a postoperative state with at least an inflammatory response around each

of the chronically implanted instruments and had catheters in at least two of their major vessels.

Since the advent of the halogenated anesthetic agents, there has been a great tendency among anesthesiologists to anesthetize the cardiovascular system, almost to the exclusion of other organ systems. This is evidenced by the fact that I notice residents frequently paying much more attention to the cardiovascular parameters than to the rest of the patient. This probably is not nearly so bad as we formerly thought, because we have found by experience that the depression of the cardiovascular system does seem to parallel the depression of the central nervous system or the production of what we call "anesthesia."

The difficulty of measuring "myocardial contractility," which is not defined in quantitative terms has led to a mass of correlative data. To use this type of evidence to make quantitative comparisons is probably not justified. However, "trends" or "patterns" developed by animal models or clinical situations may well be more easily predicted by the use of these measurements. The increasing use of computers that can process repetitive data with increasing speed can soon inundate the anesthesiologist with numbers and correlations. Thus these instruments should be used to give us matrix comparisons, tracking approaches and trend analyses. These technics may then be used to predict occurrences that the vigilant physician still may not diagnose until too late for optimum therapy.

Another very interesting portion of this paper is the report of the animals that received propranolol. Although the other cardiovascular parameters were not defined, it is stated that the change in dp/dt at least was not affected by the addition of anesthetic agents in an animal which could not respond with a change in sympathetic nervous system activity. This would also imply that the control state of the sympathetic nervous system activity may well influence the effect of the anesthetic agent on the myocardium.

Skovsted and Price[1] have demonstrated that enflurane, as well as halothane, fits into the group-2 type of anesthetic agents that cause a depression of the pressor center in the medulla with little effect on depressor reflexes. This is in contrast to ether, cyclopropane, and fluroxene, which produce a depression of the depressor reflexes with little depression of the pressor center—one of the surprising effects of enflurane, which also is an ether.

In conclusion, again I would like to congratulate Dr. Ritzman on his very sophisticated study that came up with an answer that I believe is clinically significant. Perhaps with further measurement at a clinical level, we will be able to find significant differences between the cardiovascular effects of these agents, but at present, we would have to come to the conclusion that both appear to depress myocardial contractility to a similar degree.

PHENCYCLIDINE Two cases of phencyclidine poisoning are described. Symptoms ranged from coma with hypotension to agitation and hallucinations. Treatment is supportive and a reduction of sensory stimulation. Naloxone or physostigmine were ineffective. Diazepam 0.1 mg/kg may be helpful in the severely agitated patient. Phencyclidine abuse should be considered in patients with unexplained acute psychosis, dystonic reactions, convulsions or coma. *(Tong TG, Benowitz NL, Becker CE et al: Phencyclidine poisoning. Low-Dose Intramuscular Ketamine for Pediatric Radiotherapy: A Case Report

H. LAWRENCE AMBERG, MD*
GLENN GORDON, MD†
Los Angeles, California‡

Ketamine in low IM doses was found to produce satisfactory anesthesia for radiotherapy in a pediatric patient in a series of extended treatments. Change in anesthesiologists may have been a factor in increasing apprehension and anesthetic dosage in later treatments.

THE anesthesiologist is occasionally involved in the anesthetic management of the pediatric patient for radiotherapy. Assuring exact field irradiation often entails the use of head molds or face masks and requires that the patient be unattended during the radiation treatment period.

Multiple methods of anesthetic management have been advocated. Harrison and Bennet[1] used insufflation of N_2O-O_2-halothane mixture with fair results. Browne and associates[2] tried to refine this technic by using an elaborate frame to support the airway, while the child inhaled N_2O-O_2-halothane via an oral airway. Both these methods avoided repeated intubations, but required frequent multiple halothane exposures. The widely used Toronto mixture, or "lytic cocktail" (2.75 mg/kg of meperidine, 0.7 mg/kg of promethazine, 0.7 mg/kg of chlorpromazine), has the disadvantages of prolonged induction and recovery times and relative anorexia during this period.

The advent of ketamine has offered an additional method of patient sedation with three major advantages: Frequent halothane exposures are avoided, the prolonged induction and recovery time associated with the lytic cocktails is reduced, and an adequate airway is assured while the patient is left unattended. Bree and colleagues[3] demonstrated the safety of repeated ketamine administrations in the monkey, and Corssen and Oget[4] proved the feasibility of using ketamine for repeated dressing changes in the burn patient, while Sadove's group[5] showed the excellent analgesic properties of ketamine given in low IM doses. Not until 1972, when Cronin and coworkers[6] reported the use of ketamine in radiotherapy, did ketamine supplant inhalation agents and lytic cocktails as a safe and easy method of immobilizing pediatric patients for brief painless treatments.

Ketamine dosages previously recommended for anesthesia in radiotherapy have ranged from 2.6 to 22.3 mg/kg IM, with and without premedication, averaging in the 6 to 15 mg/kg range.[6-8] We have found that small doses are feasible, with a concomitant decrease in associated recovery time and morbidity.

CASE REPORT

A 16.4-kg boy with a retinoblastoma at age 37 months was treated promptly by surgical enucleation of the left eye. Five months later, recurrence of the tumor in the left socket was noted. A thorough medical evaluation, including brain and liver scans and a bone series, failed to elicit evidence of

Paper received: 5/2/75
Accepted for publication: 7/9/75

metastases. Following a second excisional operation, the decision was made to irradiate the socket with 5600 rads.

Prior to the involvement of the anesthesia department, chlorohydrate and lytic cocktails were given without success: 1200 mg of chlorohydrate produced an ataxic state without sufficient anesthesia for treatment; a double dose of lytic cocktail (40 mg of meperidine, 40 mg of promethazine, 20 mg of chlorpromazine) produced similar effects, with the added disadvantages of markedly prolonged induction and recovery times.

The treatments required that the child be placed in a molded headrest with a loose-mesh fiberglass face mask (fig 1 and 2). During a 7-week treatment period (4/week), the patient received a total of 29 ketamine administrations: 28 sessions of 200 rads each, plus one preliminary session to determine field size and location. No premedication was administered prior to the first 13 sessions; however, to reduce the possibility of laryngospasm secondary to secretions, 0.3 mg of atropine was given orally 1 hour pretreatment for the remaining 16 sessions.

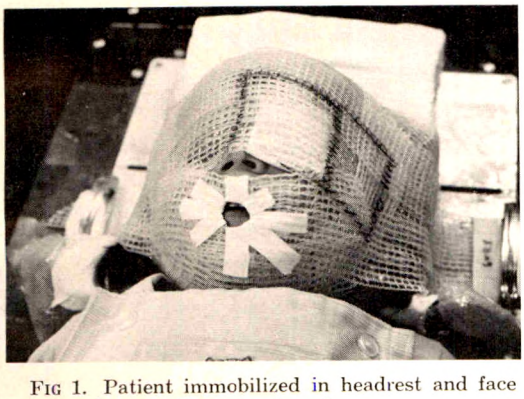

FIG 1. Patient immobilized in headrest and face mask and ready for a treatment.

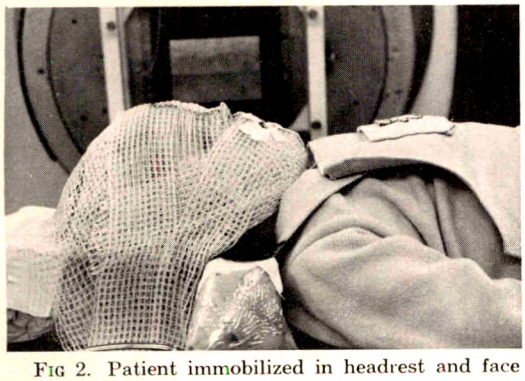

FIG 2. Patient immobilized in headrest and face mask and ready for a treatment.

Dosage.—Initially, the patient required only 2.7 mg/kg IM to produce a quiet, immobile state for the 5-minute sessions. After 5 treatments, this dosage proved inadequate and was increased to 3.6 mg/kg IM; while this was satisfactory for the next 21 sessions, an increase to 6 mg/kg IM was required for the final 3 sessions. Noteworthy was a change in anesthesiologists for these last 3 sessions.

Treatment and Recovery.—After injection in either buttock, the child remained in his mother's arms for the 2 to 4 minutes necessary to produce unconsciousness. He was then placed in the headrest, the face mask applied, and the radiation treatment begun. During the treatment, the patient was observed via closed-circuit television and directly through an observation port. Total time for treatment, from injection to the end of irradiation, averaged 10 to 11 minutes. The patient began to verbalize within 12 to 15 minutes from the time of injection and was fully recovered within 1 hour. He was able to leave the recovery area walking, escorted by his mother.

Complications.—Twice the patient produced copious secretions, necessitating suctioning and position changes; both episodes occurred in the afternoon after premedication with atropine. No treatments were prematurely terminated. Two sessions were interrupted to reposition the patient because of random hand motions and concluded without further incident. No postoperative complications, including bad dreams, hallucinations, emesis, or anorexia, were noted. Hemoglobin and WBC counts remained normal throughout the therapy, and no decrease in platelet count was observed. The patient's weight did not change over the 7-week course of treatment.

DISCUSSION

The anesthetic objectives for radiotherapy require rapid onset of action, brief duration, rapid recovery, preservation of protective reflexes with minimal cardiopulmonary depression, and good patient acceptance. We believe that ketamine fulfills these objectives better than any other drug or drug combination available.

Taylor and Towey[9] criticized the use of ketamine by demonstrating depression of the laryngeal closure reflex and radiographic evidence of aspiration under ketamine anesthesia. The dosages used, however, were not fully recorded. Dundee and Moore,[10]

using a small dose, were unable to substantiate Taylor's work. A later work by Carson and associates[11] showed frank aspiration in patients receiving 2 mg/kg IV but not in those whose dose was 1 mg/kg IV. In our patient, no signs or symptoms of aspiration or laryngospasm were observed.

Bad dreams or hallucinations have been associated with ketamine; however, this patient neither exhibited fear of the treatment nor did his mother relate any episodes of emergence complications.

One of the major disadvantages of repeated anesthetics is the disruption of eating patterns. Since the patient must, of necessity, be kept NPO prior to treatment, we chose 0900 hours as the optimal anesthetic time. Treatments were concluded by 0915 hours. By 1030 hours, the child was awake, hungry, and able to eat. He retained his appetite throughout the course of treatment, despite receiving 5600 rads and frequent anesthesia. The copious secretions noted on two occasions, when treatment was delayed until the afternoon, may have been secondary to increased anxiety and fasting, both of which contribute to an increase in salivation, aerophagia, and decreased gastric motility.[12]

Tachyphylaxis may have accounted for the increase in ketamine dosage from 3.6 to 6 mg/kg for the last 3 sessions; however, after 21 successful sessions using 3.6 mg/kg, the change in anesthesiologists seems a more likely cause. The rapport established between the patient and the primary anesthesiologist was lacking for the final 3 sessions, resulting in increased apprehension and anesthetic requirements. Anesthesiologists appreciate this correlation between reducing apprehension and subsequent anesthetic requirements, by conducting an informative preoperative visit.

N_2O Volumes Absorbed and Excreted During N_2O Anesthesia in Children

ERNEST SALANITRE, MD*
HERBERT RACKOW, MD†
New York, New York‡

Exhaled volumes were measured in 8 children during uptake and elimination of 3 percent and 75 percent N_2O, using a volume-controlled ventilator. Absorption of 75 percent N_2O during induction reduced the exhaled minute volume, which fell a mean of 16 percent in the 1st or 2nd minute and returned to normal by 15 to 20 minutes. Elimination was the mirror image of uptake; the mean increase in the exhaled minute volume was 13 percent. The concentration effect during uptake was measured (3 percent versus 75 percent N_2O) and the data were used to calculate a fall in alveolar volume of at least 8 percent by the 2nd minute of uptake. The type of ventilation (volume-limited, pressure-limited, or spontaneous) was seen to have a modifying role on the respiratory pattern caused by the absorbed and excreted volume of N_2O.

THE volume of gas absorbed into pulmonary capillary blood during N_2O anesthesia and then excreted into alveoli during elimination may cause such clinical conditions as diffusion anoxia[1] and the concentration effect.[2] Measuring volume and time course in 8 children, using a volume controlled ventilator, and ascertaining the concentration effect, previously reported only in dogs,[2,3] we used these data to calculate the reduction in alveolar volume (V_A) associated with the absorption of N_2O in clinical concentrations.

MATERIAL AND METHODS

Eight infants and children, 11 months to 6 years of age, were studied. All were without clinical evidence of cardiorespiratory disease. Data were obtained during the course of prolonged surgical procedures requiring many hours of anesthesia. Three patients underwent urethral operations, 4 had urinary bladder procedures, and one had rectal surgery.

Secobarbital, atropine, and, in one instance, meperidine were given for premedication. Induction of anesthesia was by face mask using halothane in O_2, except for an apprehensive child who received rectal sodium thiopental (25 mg/kg) followed by halothane and O_2 by mask. Succinylcholine (1 mg/kg) was administered intravenously prior to the insertion of a cuffed endotracheal tube. Air was injected into the cuff until no leakage could be heard from around the tube at an inflating pressure of about 20 torr. (This pressure was never exceeded by the inflating pressure of the respirator subsequently used.) Morphine and either d-tubocurarine or pancuronium were given intravenously, in repeated small doses, during the course of the anesthetic procedure, and ventilation was maintained with a volume-limited pediatric Frumin respirator

and a nonrebreathing system. The halothane concentration was adjusted to 0.75 percent in O_2, and anesthesia and operation continued for at least 90 minutes before the studies began. In all cases, the studies were completed before the operation was terminated.

Vital signs were monitored with a chest or esophageal stethoscope, a standard blood-pressure cuff, ECG, and a rectal or esophageal temperature probe. Body temperature was kept between 36.5 and 37.5 C by controlling the temperature of the room and by a hot and cold circulating water mattress.*

An end-tidal sample of 0.75 ml was taken from the patient end of the endotracheal tube through a fine catheter, using an intermittent sampling pump automatically timed by the respirator to sample at the end of each expiration. This sample was pumped through the microcuvettes of three infrared analyzers† in series, one adjusted for N_2O concentrations between 0 and 4 percent, one for N_2O concentrations between 45 and 75 percent, and one for CO_2. The N_2O analyzer cases were filled with 100 percent CO_2 and the CO_2 analyzer case was filled with 100 percent N_2O, to eliminate "crossover" between the two gases.

The inspiratory tidal volume ($V_{T,I}$) was adjusted until the end-tidal CO_2 concentration stabilized at about 5 percent, then the respirator controls were not changed for the entire study. The rate of cycling was 24/min. The exhaled minute volume ($\dot{V}_E$) of all subjects was measured in a pair of "9" L lightweight spirometers counterbalanced on one chain and suspended in water. A double valve system allowed one spirometer to fill with the patient's expired air while the other was emptying into room air. When the first spirometer was filled, the valves were reversed. This system made it possible to use spirometers small enough to measure the $\dot{V}_E$ of an infant, and yet have the capacity to measure for several hours. A single kymograph recorded volumes. The end-tidal sample of 0.75 ml was neglected for volume measurements.

The constancy in the output of the ventilator (the inspired minute volume [$\dot{V}_I$]) was tested by connecting the ventilator through an appropriate resistance to the spirometers for 12 minutes and measuring low $\dot{V}_I$ by a pair of "1" L spirometers and measuring high $\dot{V}_I$ by the "9" L spirometers.

*Gorman-Rupp.

†Beckman Instrument, LB-1.

The halothane vaporizer was of the Copper Kettle® type, in which O_2 bubbled through liquid halothane. Its output was appropriately diluted with a separate flow of O_2 or N_2O-O_2, which resulted in a final concentration of 0.75 percent halothane. The temperature of the vaporizer remained constant throughout the period of the study.

Each patient was ventilated initially with an inspired gas mixture of 0.75 percent halothane in O_2. After pulse, blood pressure, body temperature, end-tidal CO_2 concentration, and $\dot{V}_E$ were stable during a first control period of 10 to 20 minutes, the diluent gas was changed abruptly‡ from 100 percent O_2 to approximately 3 percent N_2O in O_2, premixed in a tank, for the first uptake study. Following 15 to 20 minutes of N_2O uptake, the diluent gas was abruptly changed back again to 100 percent O_2 for the first elimination study. End-tidal N_2O, end-tidal CO_2, and $\dot{V}_E$ were measured during both the uptake and elimination phases of the 3 percent N_2O study.

The second control period began when end-tidal N_2O concentration fell to less than 0.05 percent during the elimination phase, with 100 percent O_2 as the diluent. The same sequence was repeated, using 75 percent instead of 3 percent premixed N_2O-O_2. Similar volume measurements were made but end-tidal N_2O concentration was not monitored during elimination of 75 percent N_2O, (as the high-concentration N_2O analyzer was internally adjusted with a suppressed zero at 45 percent N_2O to attain the desired sensitivity for the uptake study).

The sampling, analytical, and recording systems have been previously described.[3] At frequent periods during each study, inspiratory gas mixture was analyzed and the infrared analyzers were calibrated against known gas concentrations delivered from previously analyzed premixed tanks.

Pulmonary equilibration curves were constructed for the uptake period of N_2O by converting the end-tidal N_2O concentrations to F_E/F_I ratios (end-tidal concentration/inspired concentration) and plotting them against time.

‡The internal volume of the respirator (estimate, 200 ml) could not be emptied and refilled instantaneously at time zero. This created an error with a time constant calculated to be about 0.14 minutes for the smallest patient whose $\dot{V}$min was 1455 ml/min (time constant, assuming $\dot{V}_I = \dot{V}_E$, = vol/flow = 200 ml/1455 ml/min = 0.14 min). The error is the same for the two concentrations of N_2O used and in any event becomes insignificant in about ½ minute.

TABLE

Maximum Change in Exhaled Minute Volume ($\dot{V}_E$) During Uptake and Elimination of 75 Percent N_2O

Patient number	Age	Weight, kg	Control $\dot{V}_E$ 3% N_2O, ml/min	Control $\dot{V}_E$ 75% N_2O, ml/min	Uptake change, %	Elimination change, %
1	11 mo	7.4	1455	1456	−13.9	+13.2
2	19 mo	8.5	1380	1428	−16.8	+11.4
3	2½ yr	13.9	1970	2059	−16.2	+8.7
4	3 yr	14.5	2179	2201	−16.6	+12.2
5	3 yr	14.6	2345	2304	−15.6	—
6	3 yr	20.0	2568	2592	−15.7	+12.2
7	5 yr	19.8	2575	2632	−17.6	—
8	6 yr	19.5	2400	2376	−17.1	+20.2
				Mean change (± SD)	−16.2 ± 1.3	+13.0 ± 4.1

RESULTS

1. Variations in the $\dot{V}_I$.—The output of the Frumin pediatric respirator ($\dot{V}_I$), as measured in each of a pair of "1" L spirometers for 12 minutes at a low V_T averaged 1377 ml ± 7.4 ml (SD) and 1315 ml ± 17 ml. As measured in each of the pair of "9" L spirometers at a higher V_T the minute output of the respirator averaged 9964 ml ± 31 ml and 10,081 ml ± 45 ml. The SD was about ± 1 percent of the $\dot{V}$min at low V_T and less at higher V_T. The pair of "1" L spirometers differed by 5 percent, while the "9" L spirometers differed by 1 percent.

2. Exhaled $\dot{V}$min During Control Periods.—During the first and second control periods in patient 1 (table) $\dot{V}_E$ was 1455 ml ± 28 ml and 1456 ml ± 21 ml, respectively. The SD was less than ± 2 percent of the $\dot{V}_E$. The control $\dot{V}_E$ of all patients is shown in the table.

3. Exhaled $\dot{V}$min During 3 Percent N_2O Uptake.—$\dot{V}_E$ in patient 1 (table) averaged 1461 ml ± 19 ml. These data are not significantly different by Student's *t*-test from the $\dot{V}_E$ during the first control period. The same pattern was found in the other subjects (table).

4. Exhaled $\dot{V}$min During 75 Percent N_2O Uptake.—This fell in the 1st minute in patient 1 from an average of 1456 to 1253 ml and then gradually returned to control by 20 minutes, a fall of 203 ml, or −13.9 percent of control. The difference from control for the first 10 minutes was −795 ml or −5.5 percent of the total control exhaled volume. The maximum change in $\dot{V}_E$ for each subject occurred in either the 1st or 2nd minute of uptake (table), for a mean value of −16.2 ± 1.3 percent.

5. Exhaled $\dot{V}$min During Elimination of 75 Percent N_2O.—$\dot{V}_E$ during elimination increased to 1649 ml in patient 1 in the 1st minute and then gradually returned to control by 15 minutes, a rise of 193 ml or +13.2 percent of control (fig 1). The $\triangle\dot{V}_E$ in the 1st 10 minutes was +773 ml or +5.3 percent of control. Mean change at the peak effect for all subjects was +13.0 ± 4.1 percent and occurred in either the 1st or 2nd minute of elimination (table).

6. Pulmonary Equilibration of 3 Percent N_2O and 75 Percent N_2O During Uptake.—The pulmonary equilibration curve (end-tidal N_2O/inspiratory N_2O, F_E/F_I, versus time) for 75 percent N_2O for subject 1 is

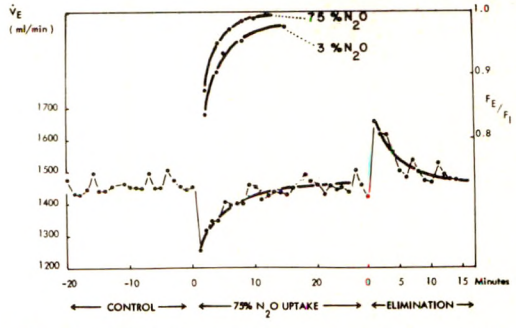

FIG 1. Exhaled minute vol ($\dot{V}_E$) during uptake and elimination of 75% N_2O, and the concentration effect. (3% versus 75% N_2O) in an 11-month-old infant.

shown in figure 1, with the 3 percent N_2O equilibration curve for comparison. The 75 percent curve is closer to inspiratory tension than the 3 percent. This same pattern was seen in each subject. The average 3 percent and 75 percent curves for all subjects and the range are shown in figure 2. The difference in F_E/F_I between the 3 and 75 percent curves is 0.07 at 2 minutes, 0.06 at 5 minutes, and 0.05 at 10 minutes.

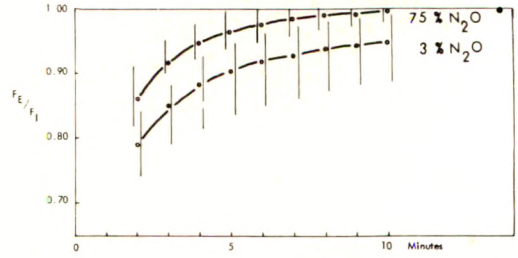

FIG 2. Concentration effect in 8 children. Circles indicate means; bars indicate range. F_E/F_I =-end-tidal concentration/inspired concentration ratio.

DISCUSSION

Uptake of 3 percent N_2O had an insignificant effect on the $\dot{V}_E$, since the volume of N_2O exchanged was small. However, the uptake of 75 percent N_2O caused a fall and then, during elimination, a rise in $\dot{V}_E$. This is a measure of the magnitude and time course of the absorbed and then excreted volume of N_2O (fig 1 and table). The size and the time course of the absorbed volume were the inverse of those of the excreted volume, but otherwise were similar. This follows the expected course of N_2O absorption and excretion and corresponds well with the calculated[4,5] and measured time course of exchange of N_2O between lung and pulmonary capillary blood in adults.[6]

The magnitude of the effect of absorption of N_2O on exhaled $\dot{V}$min can be calculated. In subject 1, the $\dot{V}_E$ fell 203 ml in the 1st minute (fig 1), or −13.9 percent of control. The average volume of N_2O absorbed per breath during the 1st minute was 13.9 percent × the control V_T of 60.6 ml, or 8.5 ml. In this 1st minute, the maximum absorbed volume in a single breath must have been higher than the average, 8.5 ml, since at time zero, absorption was zero, and then gradually reached a maximum. The mean change in the $\dot{V}_E$ at the peak effect for all subjects was −16.2 percent during uptake and +13.0 percent during elimination (table). For comparison, in the resting steady state in the infant and adult, the volume of O_2 absorbed is 4 to 5 percent of the $\dot{V}$min,[7,8] and most of this absorption effect is counterbalanced by simultaneous excretion of CO_2.

The maximum effect of absorption of N_2O on lung volume is also of interest and may be calculated from figure 2, which shows the average concentration effect for all subjects during uptake. It is important to remember that during uptake with a volume-controlled ventilator, absorption of N_2O reduces lung volume as it changes during the breathing cycle. This increases the tension of all alveolar gases, compared to what the tension would have been without any shrinking of lung volume. The magnitude of this concentration effect (3 percent versus 75 percent N_2O) at the end of the first 2 minutes can be estimated as follows:

1. At 2 minutes, for 3% N_2O,
$$\frac{F_E}{F_I} = \frac{2.49\% \text{ (measured)}}{3.15\% \text{ (inspired)}} = 0.79$$
2. At 2 minutes, for 75% N_2O,
$$\frac{F_E}{F_I} = \frac{64.5\% \text{ (measured)}}{75.3\% \text{ (inspired)}} = 0.86$$

3. If there were no shrinkage of lung volume, F_E/F_I for 75 percent N_2O would theoretically be the same as that for 3 percent N_2O (0.79) and the theoretic alveolar N_2O concentration would be 59.4 percent instead of 64.5 percent:
$$\frac{F_E}{F_I} = \frac{59.4\% \text{ (theoretic)}}{75.3\% \text{ (inspired)}} = 0.79$$

The amount of lung volume shrinkage necessary to increase this theoretic 59.4 percent N_2O to the measured 64.5 percent is:

$$\frac{59.4 \text{ ml } N_2O}{100 \text{ ml lung vol}} \xrightarrow{\text{shrinkage of lung}} \frac{59.4 \text{ ml } N_2O}{x \text{ ml lung vol}}$$

$$= 64.5\% \ N_2O. \quad x \text{ ml lung vol} = \frac{59.4 \text{ ml}}{64.5\%} = 92 \text{ ml}$$

Thus, the shrinking of lung volume was 8 percent. This represents an average change over the first 2 minutes and is an approximation only, since the increased tension due to the shrinkage must have caused further absorption of the 59.4 ml of N_2O, which in turn would cause further shrinkage of the 92 ml of lung volume. All alveolar gases (O_2, CO_2, halothane) in addition to N_2O, are affected.[3,4,9,10]

The effect on the respiratory pattern due to the absorbed and excreted volume of N_2O will vary according to the type of ventilation.[11] During uptake, absorption causes

spontaneous respiration (at constant P_{CO_2}) to have the largest inspired and expired V_T compared with other types of ventilation. A volume-limited ventilator will have the smallest inspired and expired V_T, while a pressure-limited ventilator will be in between. During elimination, excretion causes the reverse order. Since our data on the concentration effect during uptake were obtained with a volume-limited ventilator, they represent a smaller effect than would be seen with other types of ventilation.

In the first description of pulmonary absorption-excretion volume effects, Fink[1] also measured $\dot{V}$min, estimating the eliminated N_2O as being 10 to 12 percent of the total exhaled volume in the first 10 minutes during recovery from N_2O anesthesia. This is about twice the value we obtained in the same 10 minutes, but use of a volume-limited ventilator should show a smaller effect. However, unlike our study, the time course of the eliminated N_2O in Fink's study did not follow a consistent pattern of excretion: in one of the three patients whose inspired and expired volumes were studied, the exhaled $\dot{V}$min gradually increased in the first 10 minutes, reaching a peak at the end; in the second, it promptly reached a peak and then gradually decreased; and in the third, it immediately reached a plateau which was relatively stable for the entire period. These were spontaneously breathing surgical patients recovering from anesthesia. They must have experienced changing levels of anesthesia and pain, even though breathing was regular. This may have contributed to variations in ventilation and circulation that could explain the inconsistent time course.[4]

Sheffer's group[6] also studied diffusion anoxia in spontaneously breathing adults, noting a fall in P_{aCO_2} of about 10 torr which persisted after N_2O excretion had fallen. A sustained fall in P_{aCO_2} in the presence of an ever-decreasing excretion of N_2O can be explained only by a sustained increase in the inspired V_T (causing a similar increase in the expired V_T) and/or a persistent fall in CO_2 transport to the lungs. Although these variations in ventilation and circulation are the true clinical conditions of recovery, they modify the time course of elimination of N_2O and make difficult the study of the basic effect of volume change alone.

In our studies with children, during the periods of uptake and elimination of 75 percent N_2O, the higher concentration could have affected cardiac output even though no changes in pulse and blood pressure were seen. An increase in cardiac output would increase the pulmonary absorbed/excreted volume of N_2O/min and increase the concentration effect, while a decrease in cardiac output would do the reverse. However, Smith and coworkers[12] found that, in healthy adults during steady state, light halothane anesthesia, 0.8 to 1.2 percent end-tidal, with controlled ventilation and no surgical operation, there was no change in cardiac output, pulse, or blood pressure upon addition of 70 percent N_2O. Our conditions were similar though not identical.

The effects of halothane and enflurane anesthesia under conditions of normo-, hyper-, and hypocarbia on the autoregulation of cerebral blood flow (CBF) in the goat were evaluated. The goat was selected because of its unique arterial blood supply to the head and the development of a method by which CBF may be continuously measured. The study revealed that 1 MAC of halothane or enflurane anesthesia at normocarbia abolished cerebral autoregulation, CBF increasing or decreasing with increasing or decreasing peripheral blood pressure. Reduction of anesthesia to 0.5 MAC partially restored cerebral autoregulatory capability. The effect of 1 MAC and 0.5 MAC anesthesia on cerebral autoregulation of blood flow was potentiated by hypercarbia and antagonized by hypocarbia, indicating that the vascular response to blood CO_2 fluctuations remained intact.

IT IS generally presumed that halogenated hydrocarbon anesthetics have little effect on the cerebral vascular autoregulatory mechanism, despite ample demonstration that these agents are potent cerebral vasodilators.[1-6] Severe technical restraints in studying moment-to-moment cerebral blood flow (CBF) exclusive of changes in peripheral hemodynamics have no doubt confounded separation of the direct vascular action of anesthetics from their effects on cerebral regulatory mechanisms.

In this study, the effects of halothane and enflurane anesthesia under conditions of hyper-, normo-, and hypocarbia on the autoregulation of CBF in the goat were evaluated. The goat was chosen because of its unique arterial blood supply to the head and the development of a method by which CBF may be continuously measured in both anesthetized and unanesthetized animals.[7,8]

METHODS

The studies were performed on a model developed by Reimann's group[7] for the continuous measurement of ipsilateral CBF in the unanesthetized, unrestrained goat. Full anatomic descriptions of the arterial blood

supply to the goat brain and the detailed methods employed to prepare the animal for study have been presented elsewhere.[9,10] Briefly, total blood flow to each cerebral hemisphere is provided by a single external carotid artery. The external carotid bifurcates extracranially, forming the lingual and internal maxillary arteries. Two major vessels, the ramus anastomoticus and arteria anastomotica, arise from the internal maxillary and enter the cranial vault where they empty into the rete mirabile. The rete mirabile consists of a compact network of intertwined, freely anastomosing arteries permitting a high degree of contralateral communication across the midline of the brain and rete. The vascular communication is so extensive that the two structures are virtually one. Blood leaves the rete by the right and left internal carotid arteries and empties into the circle of Willis. Branches from the internal maxillary also supply blood to the extracerebral tissues via the buccinator, ethmoidal, and ophthalmic arteries.

Eight mature female goats weighing 30 to 40 kg were surgically prepared for study as follows: Anesthesia was induced with mask-administered halothane, after which the animal was intubated; artificial respiration was maintained using an Ohio respirator with 1.5% halothane in 100% O_2. An esophageal gastric tube was inserted to prevent vomiting and aspiration. A lateral incision was made along either the right or left mandible and a small portion of the mandible was removed to expose the internal maxillary, ramus anastomoticus, temporal, and dental arteries. Ligatures were placed around the internal maxillary distal to the ramus anastomoticus and on the temporal and dental arteries.

Due to their physical inaccessibility, extracerebral blood flow through the ophthalmic, ethmoidal, and buccinator arteries was obliterated by slowly injecting 1 to 2000 NIH units of thrombin in 0.5 ml of saline solution into the internal maxillary artery anterior to the site of ligation. The injected thrombin produced immediate clotting and elimination of extracerebral blood flow, as evidenced by the appearance of thrombosed vessels in the sclera and postsurgical ipsilateral blindness.

After this, a 4-mm Statham electromagnetic flow probe was placed around the internal maxillary artery for the continuous measurement of ipsilateral cerebral blood flow. A left thoracotomy was also performed and an 18-mm Statham electromagnetic flow probe was placed around the pulmonary artery for the measurement of cardiac output. A long, firm catheter was introduced into the aorta through the femoral artery for blood-gas and arterial blood pressure measurements. A similar catheter was placed in the femoral vein for the infusion of pressor drugs. All incision sites were appropriately closed for proper healing. In most cases, the animals were ready for study 2 weeks after the surgical procedures.

The presence or absence of autoregulation of CBF in the experimental animals was determined by simply increasing or decreasing systemic arterial pressure through the infusion of vasoactive agents while simultaneously monitoring CBF. In the awake animal, angiotension and/or dopamine was infused via the femoral vein catheter with a constant-rate infusion pump in sufficient concentrations to raise arterial pressure. (Neither agent separately nor in combination had any effect on CBF in the awake animal.) Sodium nitroprusside was used to lower arterial pressure. In animals anesthetized with halothane or enflurane, hypotension was produced as a consequence of the anesthetic and it was therefore only necessary to raise arterial pressure by infusing angiotensin or dopamine to verify the presense or absence of cerebral autoregulation.

Conditions of hypercarbia in anesthetized animals was produced by having the animals breathe a mixture of 10% CO_2 and air. Hypocarbia was produced by hyperventilation. Blood samples were drawn at appropriate times throughout each experiment for blood-gas analysis and gas chromatographic analysis of anesthetic concentration.

Eight animals were randomly studied under the following experimental conditions: awake; 0.5 MAC halothane anesthesia at hyper-, hypo-, and normocarbia; 1 MAC halothane anesthesia at hyper-, hypo-, and normocarbia. Six animals were studied as described but with enflurane. N_2O was not used in any of the experimental trials involving 1 MAC anesthesia and was used only when necessary during 0.5 MAC anesthesia. O_2 (100%) was used at all experimental trials except with awake animals.

RESULTS

CBF remained remarkably constant throughout an increase or decrease in MAP between 60 to 200 torr in the awake animal

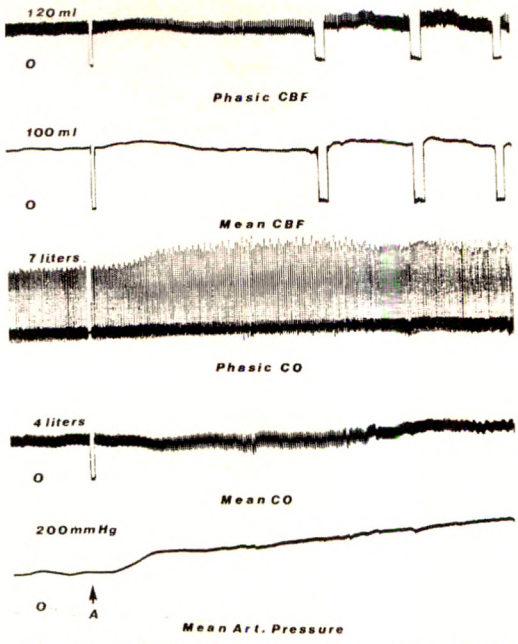

FIG 1. Effects of increasing systemic arterial pressure on ipsilateral CBF in the awake goat. Elevation in MAP to 200 torr produced only a slight increase in CBF. CBF = cerebral blood flow in ml/min; CO = cardiac output in L/min. Recording paper speed 1 mm/sec.

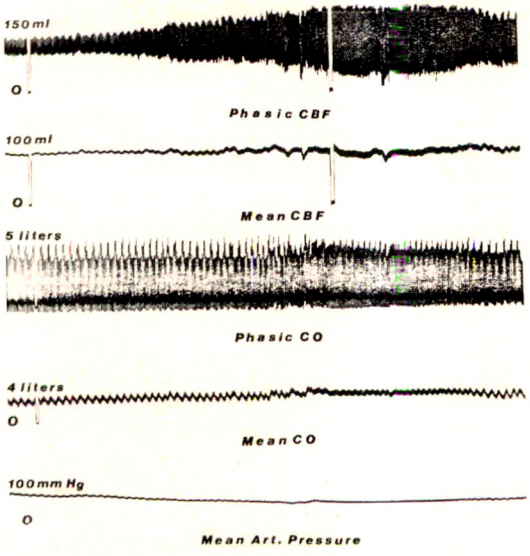

FIG 2. Effects of decreasing systemic MAP on ipsilateral CBF in the awake goat. Decreases in MAP to 50 torr produced only a slight decrease in CBF. Recording paper speed 1 mm/sec.

(fig 1 and 2). However, during 1 MAC halothane anesthesia (fig 3) under normo-, hyper-, and hypocarbia, autoregulation of CBF was abolished. With each progressive

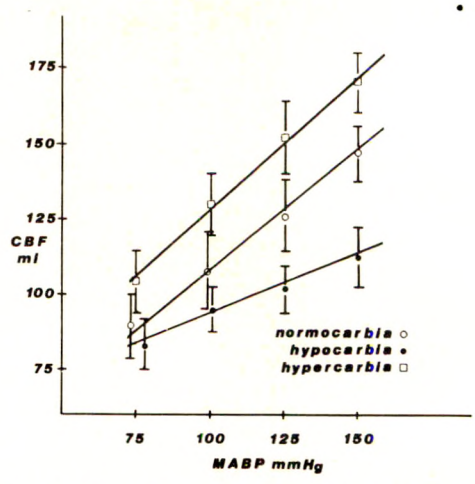

FIG 3. Effects of increasing systemic MABP on ipsilateral CBF during 1 MAC halothane anesthesia (average) 17 ± 5.6 mg/100 ml blood ± SD, n = 8) at normocarbia (average Pco_2 32.7 ± 6.2 ± SD, n = 8), hypercarbia (average Pco_2 68 ± 10.4 ± SD, n =8), and hypocarbia (average Pco_2 19.3 ± 2.6 ± SD, n = 8).

increase in MAP, there was a parallel elevation in CBF (fig 4). Compared with normocarbia, hypocarbia reduced both the magnitude and rate of change in cerebral flow. Hypercarbia increased the magnitude of CBF but did not affect the rate of change of cerebral flow. Enflurane, in equipotent anesthetic concentrations, produced similar effects on autoregulation as compared to halothane (fig 5).

Reduction of halothane anesthetic levels to approximately 0.5 MAC partially restored autoregulation of CBF. At normal blood

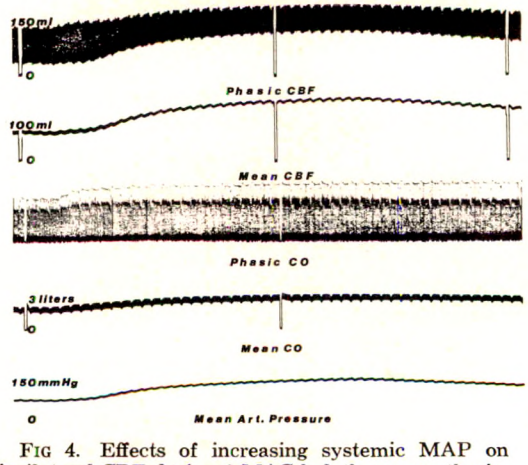

FIG 4. Effects of increasing systemic MAP on ipsilateral CBF during 1 MAC halothane anesthesia. Recording paper speed 1 mm/sec.

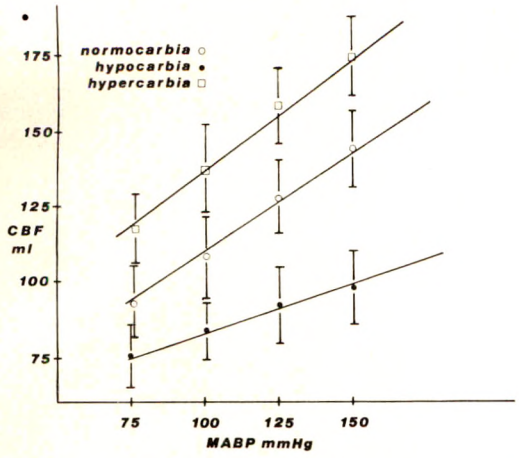

FIG 5. Effects of increasing systemic MABP on ipsilateral CBF during 1 MAC enflurane anesthesia (average 26.2 ± 8 mg/100 ml blood ± SD, n = 6) at normocarbia (average Pco_2 34.2 ± 2.3 ± SD, n = 6), hypercarbia (average Pco_2 59.1 ± 7.7 ± SD, n = 6), and hypocarbia (average Pco_2 22 ± 6.3 ± SD, n = 6).

CO_2 concentrations, CBF increased with increasing blood pressure up to a MAP of about 96 torr (fig 6). After this, CBF no longer increased, despite continued elevation in arterial blood pressure (fig 7). Presumably, the pressure at which CBF leveled off is the point in arterial pressure at which autoregulation of cerebral flow became manifest. Hypocarbia slightly reduced the "autoregulatory point" in arterial pressure, while hypercarbia elevated the autoregulatory point (fig 6).

The susceptibility of CBF to sudden changes in peripheral hemodynamics in the absence of autoregulation due to 1 MAC halothane anesthesia can be seen in figure 8.

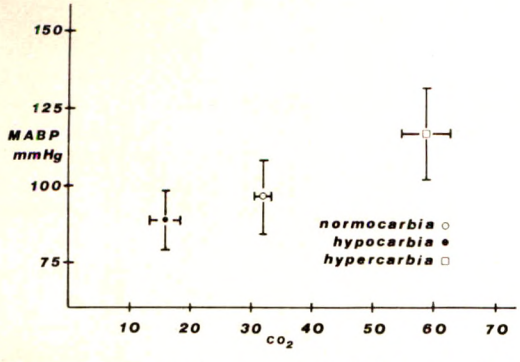

FIG 6. The point in systemic MABP above which the autoregulation of CBF became manifest during 0.5 MAC halothane anesthesia (average 8.45 ± 2.3 mg/100 ml blood, n = 8) at normo-, hyper-, and hypocarbia.

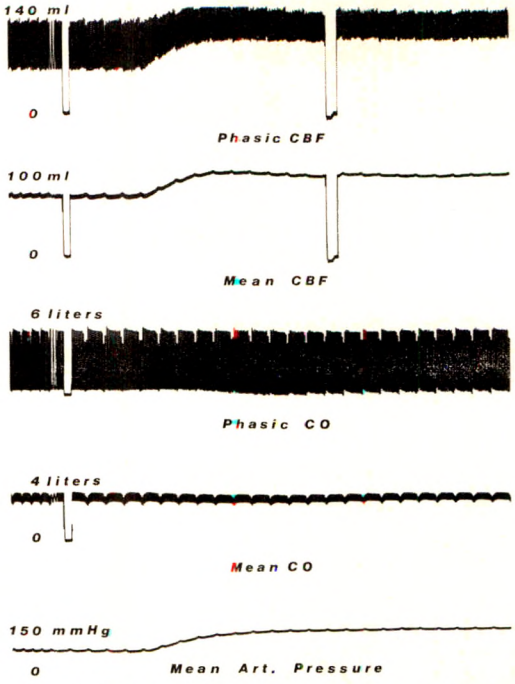

FIG 7. Effects of increasing systemic MAP on ipsilateral CBF during 0.5 MAC halothane anesthesia. Recording paper speed 1 mm/sec.

A spontaneous episode of decreased cardiac output and blood pressure was immediately reflected in CBF.

Figure 9 illustrates an atypical CBF response to blood pressure change (as compared to the typical, in fig 7) under 0.5

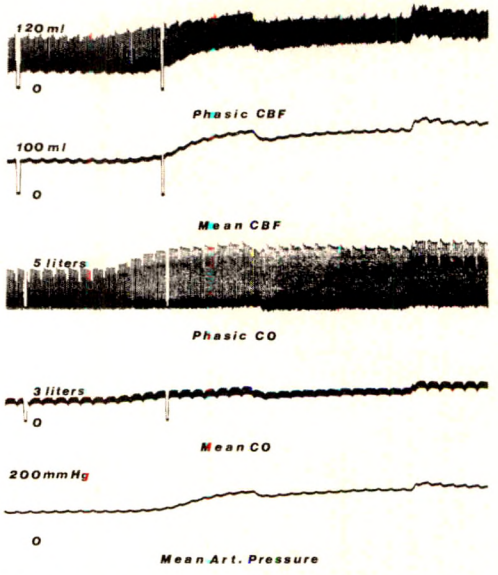

FIG 8. Demonstration of the susceptibility of CBF to sudden changes in peripheral hemodynamics during 1 MAC halothane anesthesia at normocarbia. Recording paper speed 1 mm/sec.

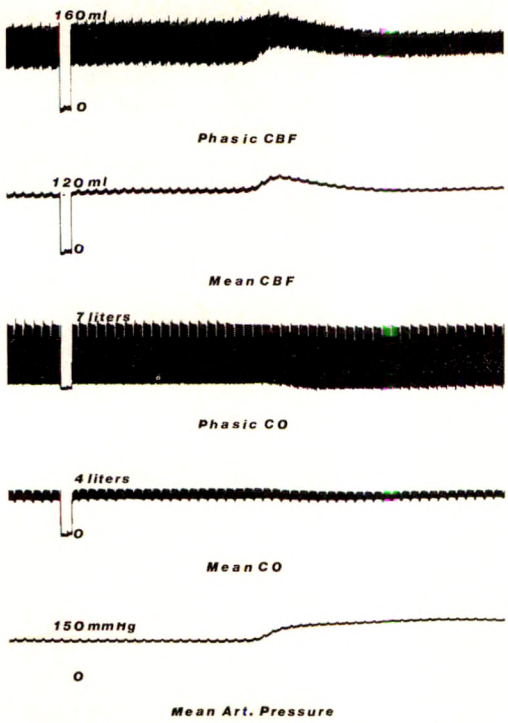

FIG 9. Demonstration of partially impaired autoregulation of CBF during 0.5 MAC halothane anesthesia shortly after induction of anesthesia. Recording paper speed 1 mm/sec.

MAC halothane anesthesia at normocarbia. In this situation, CBF returned to preangiotensin levels, while arterial pressure remained elevated. This kind of response was generally seen shortly after the induction of anesthesia and was usually not demonstrable after approximately 20 minutes of anesthesia. Presumably, in the early phase of anesthesia, the brain and vascular tissues had not equilibrated in terms of anesthetic concentration with the blood and therefore retained some autoregulatory capability.

DISCUSSION

Autoregulation of CBF may be described as the ability of the brain to maintain an adequate flow consistent with its metabolic needs, independent of changes in peripheral hemodynamics. Ordinarily, in many species, of animals and man, changes in MAP, between 60 and 150 torr, have little effect on CBF[11,12] However, the goat has a greater autoregulatory range, and MAP changes up to 200 torr produced little effect on the magnitude of CBF (fig 1). The ability of the goat to maintain a constant cerebral flow at extremely high arterial pressures is due to the rete mirabile being distal to the circle of Willis, where it damps excessively high peripheral arterial pressures but has little effect on pressures between 50 and 150 torr.[13]

As seen in this study, halothane and enflurane anesthesia impair the cerebral autoregulatory mechanism. Light anesthesia, eg, 0.5 MAC, at normocarbia reduces the effective range of MAP over which CBF is regulated (fig 6 and 7). Up to a mean pressure of 96 torr, CBF passively follows peripheral changes in pressure. Above 96 torr, autoregulatory capability appears intact, since CBF exhibits no further increase despite continued elevation in peripheral pressure. Increasing the depth of anesthesia to 1 MAC at normocarbia totally eliminates effective cerebral autoregulation (fig 3, 4, and 5). CBF increases linearly with increases in MAP from 60 through 150 torr.

CO_2, the most potent cerebral vasodilator known, is reportedly[2,14] potentiated by halothane anesthesia. However, it is not clear from these reports whether the observed halothane-CO_2 "potentiation" was simply addition of their vasodilative effects or true potentiation (which would require that the two in combination produce a greater effect than the sum of their individual effects). In the present study, the problem of halothane-CO_2 "potentiation" could not be resolved, but it was evident that the level of blood CO_2 had considerable impact on the state of cerebral autoregulation during anesthesia. The effect of CO_2 was best seen in situations of 0.5 MAC anesthesia (fig 6).

Hypocarbia enlarged the range of arterial pressure over which CBF was regulated as compared with normocarbia, while hypercarbia reduced the range. Since decreased CO_2 decreased the point in peripheral pressure at which autoregulation began, while increased CO_2 increased that point, it would appear that the vascular effects of CO_2 were merely superimposed on the anesthetic effect. This likelihood was further substantiated by the demonstration that elevated blood CO_2 during 1 MAC anesthesia increased the magnitude of CBF, but did not alter the rate of CBF increase. However, hypocarbia not only reduced the magnitude of CBF but significantly lessened the rate of cerebral flow increase (fig 3 and 4). The latter observation would imply that the vasoconstrictive effect of hypocarbia predominates over the vasodilative effects of halothane or enflurane anesthesia.

These findings suggest that, independent of other considerations, hypocarbia would be a desirable adjunct to anesthetic management involving patient requiring positional changes.

Most attempts to explain the mechanism of CBF autoregulation fall into one of 3 hypotheses: (1) the vasomotor theory,[15] (2) the metabolic theory,[16] or (3) the neurologic reflex theory.[17,18] All three explanations lack definitive experimental evidence and are based primarily on inference. Evidence for a neurologic reflex mechanism in the control of CBF is of such an indirect nature that it is difficult to accept. The metabolic theory proposes that a rapid build-up of acid metabolites induces vascular vasodilation, but the mechanism of cerebral vascular vasoconstriction in response to peripheral pressure increases is not as easily explained and is therefore a major weakness in this theory. The vasomotor theory is perhaps the most logical and is thus the most generally accepted.

Simply stated, the vasomotor theory requires that the smooth muscle layer of the cerebral vessels act as stretch receptors atuned to the state of intraluminal pressure. As intraluminal pressure increases, the smooth muscle layer contracts and as pressure drops, the smooth muscle relaxes. While the idea appears plausible, the present study would indicate that refinement of this concept is necessary to comply with experimental observation.

As demonstrated, 1 MAC of halothane or enflurane anesthesia abolishes autoregulation, suggesting relaxation and/or paralysis of cerebrovascular smooth muscle. However, since the cerebral vessels retained the ability to respond to changes in blood CO_2 levels during 1 MAC anesthesia, relaxation or paralysis of vascular smooth muscle would seem unlikely as an explanation for the loss of autoregulation. It is apparent that the cerebrovascular response to systemic arterial-pressure fluctuations and blood CO_2 changes are initiated by separate, specific pathways but are manifested by the same mechanism, the contraction or relaxation of vascular smooth muscle.

Specificity suggests the presence of discrete receptors or mechanisms for both physiologic responses. Within the autoregulatory pathways, these receptors apparently are not homogenous, or they are physically distributed in such a way as to render some of them less accessible to anesthetic interaction than others. The response seen in figure 9 could be explained by a receptor fitting this description. (It should be understood that the term "receptor" as used here refers to either a specific molecular configuration or a particular metabolic event which, when appropriately agonized, would lead to vascular smooth muscle activity.) The change in CBF following an increase in arterial blood pressure during 0.5 MAC halothane anesthesia at normocarbia (fig 9) was only seen shortly after the induction of anesthesia and presumably represents a situation in which the cerebral vascular and brain tissue had not been completely saturated with anesthetic, thus retaining some autoregulatory capability. Clearly, then, the autoregulation of CBF is not an "all-or-none" process. Partially impaired autoregulation of CBF has also been reported in situations of brain injury[19] and hypoxia.[20]

Earlier reports[14,21] have asserted that halothane anesthesia does not disrupt cerebral autoregulation. These assertions were based on static hemodynamic observations. A single measurement of CBF at any particular peripheral arterial pressure gives no information concerning the status of cerebral autoregulation. Assessment of the integrity of autoregulation during anesthesia requires multiple CBF measurements as peripheral pressure changes.

ACKNOWLEDGMENT

The authors extend their gratitude to Mss C. Seals and A. Jozefiak and to Mr. D. Visintine for exceptional technical assistance.

Guest Discussion

EDWARD A. BRUNNER, MD, PhD
Department of Anesthesia
Northwestern University
Medical School
Chicago, Illinois

It may be worthwhile to consider the meaning of the term "autoregulation," as used in this paper. The authors describe it as "the ability of the brain to maintain an adequate flow consistent with its metabolic needs. . . ." Most physiologists would use a more restrictive definition which would relate flow, perfusion pressure, and vascular resistance. Metabolic considerations would be relegated to a possible mechanistic role.

The volume of flow (F) through an organ is pressure (P) dependent so long as the vascular resistance (R) in that organ is constant: $F = \frac{P}{R}$.

Under normal circumstances in the brain, however, the cerebrovascular resistance is not constant but is itself a function of perfusion pressure. Normally, as perfusion pressure increases, the cerebrovascular resistance also rises so that, although flow may increase, the increase is less than it would have been had resistance remained constant. Flow, then, tends to remain *relatively* constant despite alterations of perfusion pressure, within set limits. This is what is meant by the term "autoregulation." The reasons for these relationships of flow, pressure, and resistance are not yet clearly defined, but mechanisms based on both metabolic and myogenic factors have been postulated. Such considerations are beyond the scope of this discussion.

The "pressure" which functions in the autoregulation of CBF is the effective perfusion pressure, *not* the arterial pressure. The effective perfusion pressure in the brain differs from the arterial pressure by a value equal to the sum of the venous pressure plus the cerebrospinal fluid (CSF) pressure.

$$\text{Perfusion pressure} = \text{arterial pressure} - \left(\begin{matrix}\text{venous} \\ \text{pressure}\end{matrix} + \begin{matrix}\text{cerebrospinal} \\ \text{fluid pressure}\end{matrix}\right)$$

Note that I have not introduced the term "mean pressure" into the discussion at this point. The reason is that the role of pulsatile or nonpulsatile pressures has not yet been clearly defined in autoregulation of cerebral blood flow. Held and his coworkers[1] have shown that autoregulation is impaired by changing from pulsatile to

nonpulsatile perfusion pressure when a constant mean pressure is maintained, indicating that the character of the pressure curve as well as the absolute level of mean pressure is probably important in cerebral autoregulation.

In view of the factors cited above, studies purporting to investigate autoregulation or autoregulatory mechanisms should include measurements of venous pressure and CSF pressure in addition to the determination of arterial pressure, so that a determination of the perfusion pressure can be made. Additionally, some measure of the pulsatile character of the pressure wave should also be made in order to assess alterations in its character, to determine if this factor has an effect on measured alterations in the autoregulatory mechanism.

In applying these considerations to the study at hand, one would like to know whether measurements were made of venous pressure in the great veins draining the brain or of the CSF pressure. It would also be of interest to know if only the mean arterial pressure was recorded, as indicated in the figures, or whether the pulsatile character of the pressure wave was also recorded. These are important questions, since Ekström-Jodal's group[2] found that autoregulation did not occur in response to a reduction of perfusion pressure produced by alteration of venous pressure, but that it did occur when equivalent or greater reductions in perfusion pressure were produced by decreasing the arterial pressure.

Moreover, impairment of cerebral autoregulation has been produced by alteration from pulsatile to nonpulsatile perfusion pressure while maintaining mean pressure constant.[1] These factors must be fully considered before the importance of the findings reported in this study can be adequately evaluated. If, in fact, these factors have been adequately controlled in this study, the results will have great clinical implications to practicing anesthesiologists.

REPLY TO DR. BRUNNER'S COMMENTS

ANTHONY IVANKOVICH, MD

I thank Dr. Seldon for this opportunity to respond to Dr. Brunner's discussion, since time did not permit a reply after Dr. Miletich's oral presentation.

One could agree with Dr. Brunner's comments on the definition of "autoregulation;" however, after lengthy discussion, the authors chose a definition in accordance with that of Guyton:[1] "The term 'autoregulation' means regulation of blood flow through each local tissue in response to the tissue's own need for flow . . . to supply the tissue's needs for nutrients, no more, no less." My own preference for a definition is similar: "Autoregulation is the intrinsic tendency of an organ to maintain constant blood flow despite changes in arterial perfusion pressure."

I agree with Dr. Brunner's equation for "effective perfusion pressure." Theoretically, it is the pressure gradient forcing blood through cerebral vessels, being essentially the difference between mean arterial and mean venous pressures. However, I do not concur with Dr. Brunner's interpretation of the importance of the venous and CSF pressures in modifying the effective cerebral perfusion pressure. These pressures are comparatively small (0 to 6 torr and 10 to 20 torr, respectively); thus, for all practical purposes, perfusion pressure and MAP are essentially equivalent.

In several of our initial experiments, we measured the venous and CSF pressures and found that they increased only slightly during anesthesia. Following angiotensin or sodium nitroprusside injections, these pressures showed only minimal changes, compared with considerable changes in arterial pressure. In our experiments, changes in venous and CSF pressures had a negligible effect on perfusion pressures. Therefore, and since chronic catheterization of the jugular vein could lead to thrombosis and obstruction of cerebral venous outflow, we did not perform these measurements routinely.

There is ample experimental evidence that CBF is independent of perfusion pressure over the physiologic range (60 to 160 torr). Jacobson and coworkers[2] showed in dogs that when CVP was raised to 50 cm H_2O by constricting the superior vena cava, producing a reduction in effective perfusion pressures as low as 60 torr, there was no reduction in cerebral blood flow. In awake

man, Moyer and associates[3] demonstrated that when the jugular venous pressure was increased to 30 cm H_2O by inflating a cuff around the neck, causing a reduction in calculated perfusion pressure to 50 torr, there was no significant change in CBF.

The study by Ekström-Jodal's group,[4] cited by Dr. Brunner, is at variance with the above findings, since they reported a reduction in CBF when perfusion pressure was reduced by an increase in venous pressure (balloon in right atrium), but no change in CBF when perfusion pressure was reduced by arterial hypotension (bleeding). An important distinction in methodology between these studies is that the latter was performed with the brain surface exposed and covered by a plastic dome, perhaps requiring deep pentobarbital anesthesia, while extensive surgery may have resulted in cerebral trauma. In order to further amplify and clarify the lack of effect of changes in venous and CSF pressures on cerebral autoregulation, the reader is referred to two excellent monographs.[5,6]

As to Dr. Brunner's observations on the term "mean arterial pressure," and its implications in his reading of the pulsatile-nonpulsatile experiments of Held and coworkers,[7] MAP is widely used in the literature in reference to such measurements as cardiac output, peripheral vascular resistance, arterial pressure, right atrial pressure, etc, and there is a nearly universal use of "mean" arterial or perfusion pressure in correlation with changes in cerebral blood flow.[8]

The tracings in our figures show MAPs and mean flows derived by electronic integration of the phasic pressures and flows. The phasic flows are also shown on all tracings. Absence of the phasic arterial pressure on the tracings may have been misleading. It should be clear from our experimental design that the experiments were performed in the milieu of a physiologic pulsatile perfusion, as reflected by the phasic alterations in CBF shown in all the tracings. To further clarify this point a phasic arterial pressure tracing is shown here in the figure.

A careful reading of Held's paper reveals that even in the case of nonpulsatile perfusion, the ability to autoregulate is maintained, but at a higher flow level than pulsatile flow. These investigators concluded that ". . . cerebral autoregulation responds to both qualities of pressure: its pulsations and its constant component."

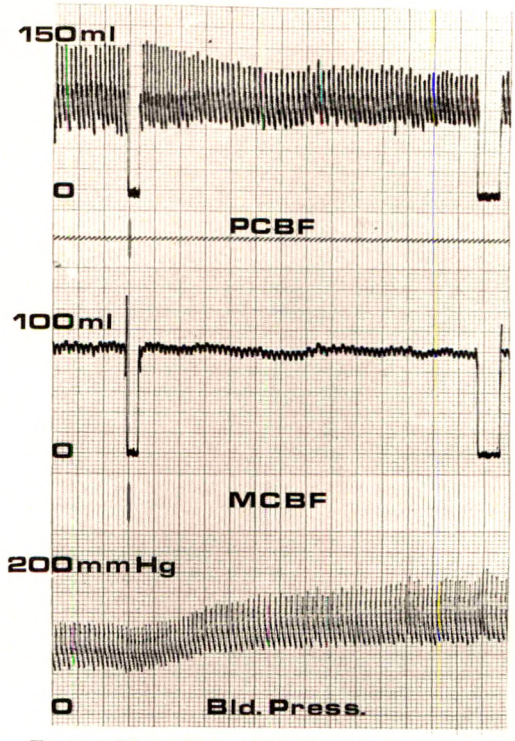

FIGURE. The effect of angiotensin infusion on phasic cerebral blood flow (PCBF), mean cerebral blood flow (MCBF) and phasic arterial blood pressure in the unanesthetized goat. Angiotensin produced an immediate increase in phasic arterial pressure, decreased the magnitude of phasic cerebral flow, but had no effect on mean cerebral flow.

I hope that I have adequately answered the questions raised by Dr. Brunner. We feel that our experiments represent a carefully controlled study which indicates that halothane and enflurane anesthesia do, in fact, impair cerebral autoregulation in the goat. Recently, Murphy, for Wollman and associates,[9] indicated that autoregulation of CBF in man appeared to be lost during anesthesia with halothane and enflurane. This supports our findings and further emphasizes their clinical significance.

UMBILICAL ARTERY CATHETERIZATION Catheterization of the umbilical artery for monitoring critically ill neonates is standard practice. The authors report 15 major complications in 165 neonates related to an umbilical artery catheter. Arterial occlusion produced visceral infarction in 12 patients and vascular perforation caused hemoperitoneum in 3 patients. The duration of catheterization in these 15 neonates was 3 times that in the other 150 infants. The potential for visceral infarction increased as the catheter tip was placed more cephalad in the aorta. Roentgenographic confirmation of catheter tip location below the kidneys, avoidance of catheter manipulation and removal when no longer needed should reduce the incidence of iatrogenic complications. *(Marsh JL, King W, Barrett C et al: Serious complications after umbilical artery catheterization for neonatal monitoring. Successful Use of a Reduced Dose of Protamine After Cardiopulmonary Bypass

ANITA V. GUFFIN, MMS*
RONALD W. DUNBAR, MD†
JOEL A. KAPLAN, MD‡
JAMES W. BLAND, JR., MD§
Atlanta, Georgia‖

The dose of protamine necessary to reverse heparin was examined in 60 patients. Half the patients (controls) received a reversal dose of protamine equal to the entire amount of heparin given them, while half received a reversal dose based on a heparin half-life of 2 hours. Postoperative chest drainage for the first 12 hours and for 48 hours was markedly reduced in patients given the reduced dose of protamine. Platelet counts were higher and postoperative clotting studies varied less from control in patients receiving the smaller dose of protamine. The authors suggest reevaluation of the dose of protamine necessary to reverse the anticoagulant effects of heparin in patients for cardiopulmonary bypass, since larger doses of protamine may contribute to the conditions which increase postoperative bleeding.

A MAJOR problem following cardiopulmonary bypass is reversal of the anticoagulant. Heparin is recognized as the most effective anticoagulant, and protamine sulfate, originally recognized as an anticoagulant itself, is now generally used to reverse the anticoagulant action of heparin.[1-3]

Whether excess protamine actually contributes to postoperative bleeding is still controversial.[4-6] In general, dosage is 1 to 4 mg of protamine sulfate per milligram of heparin administered during the procedure. Our study investigated the use of a reduced dose of protamine, to determine its effect on postoperative bleeding and clotting.

METHODS

Two groups of 30 patients undergoing coronary artery bypass procedures were studied (table 1). All patients were anesthetized with morphine sulfate (0.3 to 0.5 mg/kg), diazepam (0.2 to 0.3 mg/kg), and N_2O-O_2, with either pancuronium bromide or d-tubocurarine for relaxation. All had two intravenous infusions. Central venous and direct arterial pressure, ECG, and esophageal and rectal temperatures were monitored, and arterial blood gases were measured throughout the procedure by a Radiometer Copenhagen Model BMS3 Blood Gas Analyzer. Serum potassium was measured every

B (experimental group)	30	47.5 ± 2.4	67.0 ± 2.6

No significant differences.

30 minutes during the procedure and potassium chloride was administered to maintain a level of approximately 4.5 mEq/L.

Beef lung heparin (3 mg/kg) was administered initially, and 1.5 mg/kg was given at 2-hour intervals during bypass. Body temperature was reduced to 28 to 30° C for the greater portion of the bypass period. A Bentley-Temptrol oxygenator was used for all patients. The priming volume of the pump consisted of 1500 ml of Normosol®, 500 ml of dextran, 22.5 gm of mannitol, and 500 ml of whole blood. Following bypass, each patient received an average of 3 units of whole blood. In group A, 6 patients received 2 units of fresh-frozen plasma and 12 patients received 5 units of platelets. In group B, 7 patients received 2 units of fresh-frozen plasma and 4 patients received 6 units of platelets. All blood products were administered following collection of blood samples for coagulation studies.

Following bypass, group A was given a reversal dose of protamine that was a milligram-for-milligram equivalent of the entire amount of heparin given during the procedure. Group B was given a reduced dose of protamine based on a heparin half-life of 2 hours. Calculations were based on a straight-line decay that assumed 75 percent of the original heparin remained after 1 hour and 50 percent remained after 2 hours. We administered heparin in half the original dose after 2 hours and assumed this would bring the patient again to full heparinization.

For example, a patient given 200 mg of heparin at 1000 hr would receive another 100 mg for reheparinization at 1200 hr. At 1300 hr, a patient in group B would receive 150 mg of protamine to reverse the residual heparin. This assumes 75 percent of the original dose would require reversal. In contrast, a patient in group A would receive 300 mg of protamine.

Protamine was administered over 10 to 15 minutes, and clotting studies were drawn 10 minutes after the patient had received the total dose of protamine. Chest drainage was measured for the first 12 hours postoperatively and for the total indwelling of the chest tubes (approximately 48 hours). Coagulation parameters studied were prothrombin time, partial thromboplastin time, and platelet count. All statistical comparisons were made by Student's *t*-test.

RESULTS

The control group (A) received significantly more heparin than the experimental group (B), due to the slightly greater weight of the patients. Group B received less protamine than group A; this difference was highly significant ($p<0.005$) (table 2).

Group B patients showed significantly less variation of prothrombin time and partial thromboplastin time (table 3). These differences were both significant ($p<0.005$). The platelet count averaged 40,000 higher

in group B ($p<0.005$), in which group the lowest platelet count postoperatively was 79,000. Eight patients in group A had platelet counts of less than 60,000, and 1 patient had a platelet count of 6400 after bypass. Platelet function was not studied.

Postoperative chest drainage of blood was also significantly less in the experimental group with a reduced dose of protamine (table 4).

Cardiopulmonary bypass time was about the same for both groups (table 5), but time after bypass was considerably shorter in group B ($p<0.005$), probably because of less bleeding and oozing, permitting quicker closure of the chest. Total surgical time was also 1 hour less in group B ($p<0.005$).

DISCUSSION

Various reports show protamine dosage for heparin reversal to range from none[7] to 4 times the amount of heparin given during the operation.[2,4,5] Frequently, the reversal dose of protamine equals the total amount of heparin given.[4,5]

Heparin is repeated in doses equal to one-half of the original dose at time intervals of 1 to 2 hours, depending on the dose schedule used by different authors.[4,8,9] This rationale is based on studies showing the half-life of heparin to be dependent on temperature and dosage, and to increase with larger doses.[9,10] Therefore, unless heparin has just been administered, it is recognized that some of the heparin has been catabolized, bound, or excreted, leaving only a portion of the original amount to be reversed.

Though the half-life decay of heparin is uneven, we used a straight-line approximation based on a half-life of 2 hours. The half-life of 1, 2, and 4 mg/kg injected IV is 56, 96, and 152 minutes, respectively.[10] Previous studies have shown a half-life of 3 mg/kg to be 1.75 hours at 37 C and 2.5 hours at an average temperature of 22 to 23 C.[9] Since all our patients were exposed to a period of decreased temperature of 28 to 30 C during the procedure, the half-life of heparin (3 mg/kg) was estimated to be 2 hours.

The dose of 1 mg of protamine for each milligram of heparin administered to our controls was based on studies showing that protamine is not a significant anticoagulant in moderate overdosage, and that this dose was in a safe range.[4] In fact, Ellison's studies[4] suggest that overdosage of protamine might be given to ensure complete reversal of heparin without threat of the anticoagulant effects of protamine. However, this amount was 2 to 5 times greater than the calculated dose would have been using a heparin half-life of 2 hours. Other reports indicate only minimal protamine inhibition of clotting.[1,2,6,8] Comparing the dose of protamine given to our controls with the dose that would have been administered according to the protocol for the experimental group, the excess protamine administered averaged 203 mg per patient.

Though heparin rebound has been pointed out as a possible threat with small doses of protamine,[11] our study seems to indicate that the rebound may be only a laboratory value, and that it does not significantly increase postoperative bleeding. This is shown by the 50% reduction in 12-hour chest drainage and the 45% reduction in 48-hour chest drainage for group B.

Some evidence[8] indicates that protamine can cause platelet agglutination and disappearance of platelets; this may explain why platelet count was greater by approximately 40,000 in the group with the reduced

TABLE 5
Surgical Times (Minutes)

Interval	Group A Mean ± SE	Group B Mean ± SE	Significance*

protamine dosage. Thrombocytopenia sometimes follows cardiopulmonary bypass; administration of excess protamine may aggravate this condition. However, no laboratory verification of this has been documented.

In summary, we believe the dose of protamine used to reverse heparin during cardiac surgery needs reassessment. Smaller doses led to decreased postoperative bleeding in our study, and there was no clinically apparent heparin rebound. We believe heparin activity and protamine reversal should be more closely monitored intraoperatively by frequent coagulation tests. Studies along this line are currently in progress.

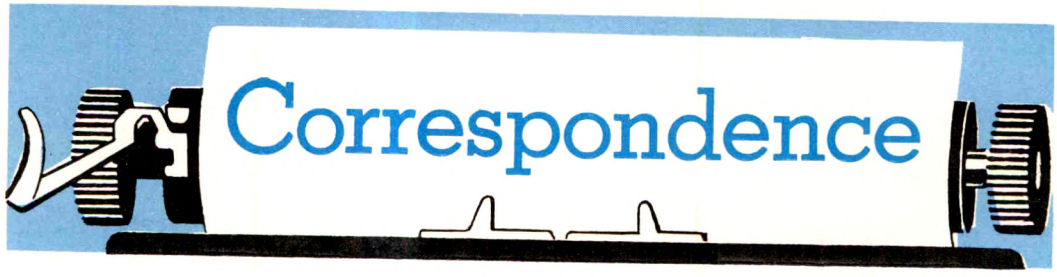
THE INFLUENCE OF THE ROUTE OF ADMINISTRATION ON THE CLINICAL ACTION OF DIAZEPAM. In a "double-blind, double-dummy" study in 200 adult women, closely matched as to age, weight, and physical fitness, diazepam by mouth, buttock, and/or thigh (IM) was investigated for comparison of efficacy, side effects, and especially pain of injection. The systemic analgesic effect of combining oral and IM diazepam was not notably greater than that of the single oral dose. As the injection of diazepam was followed by an unacceptably high incidence of pain, the oral administration of this drug should be the route of choice. *(Assaf, Dundee, Gamble. Anaesthesia 30:152-158, 1975.)*



To the Editor:

I feel compelled to comment on the recent article by Howland and associates, "Fibrinogen and albumin deficiencies associated with packed red blood cell transfusions, (Anesth & Analg 54:89-93, 1975) which contains errors and misconceptions that must not go unchallenged. The authors describe a liver-transplant patient who received 35 units of packed red blood cells resuspended in normal saline solution during the course of a 14-hour operation. They state that "packed cells were selected in preference to whole blood in an effort to avoid white-cell interference with immunologic mechanisms." If by this somewhat ambiguous statement they mean to imply that the white blood cell content of packed red blood cells, as the term is commonly used, differs in any way from that of whole blood, they are mistaken. Of blood products commonly available, only frozen red blood cells or leukocyte-poor (buffy-poor) red blood cells have most of the white blood cells removed. Although not stated in the article, I assume that the reason the authors chose not to administer platelet concentrates to their patient (a product clearly indicated in large quantities for any patient receiving 35 units of blood during a 14-hour surgical procedure) was their reluctance to expose their patient to the transplant antigens which platelets are known to carry as well as to the white blood cells inevitably present in platelet concentrates.

Although lamenting the absence of fibrinogen in purified protein fraction, they fail to mention the use of single-donor plasma as a suitable product for volume expansion. Single-donor plasma contains normal levels of fibrinogen as well as all other plasma

proteins. Their reluctance to administer single-donor plasma may be related to the minimal hepatitis risk of the product, a risk not present with albumin or purified protein fraction. Their patient had a substantial intraoperative exposure to blood, and judicious use of single-donor plasma, in my opinion, would have been warranted, particularly when the hepatitis risk is weighed against the clinical consequences of the greatly depressed fibrinogen level their patient displayed postoperatively.

I can find no fault with the authors' conclusion that if you remove the plasma from a unit of whole blood and replace it with normal saline, the total protein and fibrinogen in the unit will decline.

Bruce A. Friedman, MD
Associate Director, Blood Bank
University Hospital
University of Michigan
Ann Arbor, Michigan

To the Editor:

In reply to Dr. Friedman's letter concerning the article "Fibrinogen and albumin deficiencies associated with packed red blood cell transfusions," we inadvertently omitted to say that the packed cells in the case under discussion were white-cell poor.

Apropos of the necessity for administering platelets during massive blood replacement, we differ from Dr. Friedman. Although bank blood is deficient in platelets and the platelet count does fall in these patients, we have been able to control bleeding very effectively without the use of platelets. Platelets are employed only in those cases in which the thromboelastograph indicates poor platelet function. The latter cases are very few.

To the Editor:

I wish to comment on the excellent paper, "Plasma Concentration of Lidocaine after Endotracheal Spray," by Chu and associates (Anesth & Analg 54:438-441, 1975).

In 1972, at the Fifth World Congress of Anaesthesiologists, we[1] reported on a similar investigation measuring the uptake of lidocaine from the trachea. A summary of the work follows:

Thirty patients admitted for minor nose and throat surgery were premedicated similarly with hydroxyzine, 50 mg; pentobarbital, 1.5 mg/kg; and atropine, 0.4 to 0.8 mg IM, 1 hour before operation. Anesthesia was induced with thiopental, 5 mg/kg, and tracheal intubation facilitated with succinylcholine, 1.5 mg/kg. Lidocaine in concentrations of 2 or 4% was instilled via a Steiner cannula into the trachea at a dose of 2 mg/kg prior to intubation. Anesthesia was maintained throughout the procedure with N_2O-O_2 (50-50) and 1 to 2% halothane. During this project, no toxic effects of lidocaine were recorded.

Venous blood samples were collected at 0, 5, 10, 20, 30, 60, 90, and 120 minutes. The blood samples were centrifuged and the serum extracted for lidocaine and its metabolites by the method of Edhorn.[2]

Analyses were with a series-104 gas-liquid chromatograph (WG Pye), equipped with dual flame ionization detector and a Philips PM 8000 recorder. The injection part and detector were maintained at 280 C and the oven at 170 C for the first 5 minutes after injection and then programmed at 12 C/min to 240 C. A Pyrex-glass coiled column, 1.5 m long with 0.635 cm OD, packed with Chromsorb(R), was used for analyses. Gas flow rates were H_2, 50 ml/min; air, 600 ml/min; and N_2, 40 ml/min.

A significant and continual rise of lidocaine and its metabolites in plasma resulted throughout the first 30 to 60 minutes, followed by a gradual decline in plasma levels thereafter. Similar results were obtained with 2 and 4% lidocaine.

The plasma level of lidocaine rarely exceeded 1 μg/ml. Glycine xylidide was by far the major metabolite seen in the plasma, with blood levels frequently exceeding 8 μg/ml. Monoethyl glycine xylidide plasma levels were below those of lidocaine and only occasionally was the parahydroxy metabolite observed at the lower limits of detection (0.2 μg/ml). The peak blood levels of lidocaine in the 30 patients ranged from a low of 0.1 μg/ml to a high of 2.0 μg/ml.

It appears that the work of Chu's group confirms our finding that the uptake of lidocaine from the upper trachea under the conditions described is slower than when given IV.

In 1965, Telivuo[3] also found a slow absorption of lidocaine from the respiratory tract with spontaneous ventilation.

To the Editor:

Thank you for sending me a copy of Dr. Smith's letter. Dr. Smith and I both agree that the rate of absorption of local anesthetic administered through endotracheal spray in supine anesthetized patients shows significant delay as compared with the IV route.[1,2] The differences between the lidocaine blood concentration in Dr. Smith's group of patients and ours may be due to dosage (2 mg/kg versus mean 3.3 mg/kg body weight), and the cannula used (Steiner versus LTA).

The metabolic pathway of lidocaine was well illustrated by DiFazio and Brown.[3] The major metabolite of lidocaine was found to be monoethylglycinexylidide (MEGX),[3,5] 20 to 76% of the lidocaine level. The level of glycinexylide (GX) was lower, 12 to 16% of the lidocaine concentration. Both MEGX and GX are pharmacologically active and may contribute to the CNS stimulation by lidocaine.[4,6] On a weight basis, MEGX has 88% and GX 54% the antiarrhythmic potency of lidocaine, and GX was 27% as potent as MEGX. In man, 41 to 58% of the administered GX was excreted unchanged by kidneys, 4.3 to 4.8% underwent metabolic transformation and appeared in urine as conjugates of xylidine and p-OH xylidine, and the fate of the rest was unknown.

The results obtained by Dr. Smith's group showed that GX was by far the major metabolite and its plasma concentration often exceeded that of lidocaine. This is an interesting finding. More studies are needed to understand the difference in the

pharmacokinetics between IV and endotracheal routes of lidocaine administration.

I appreciate very much Dr. Smith's comments.

To the Editor:

In the May-June 1975 issue, Forestner and Raj[1] report on the inadvertent injection of a 2% solution of thiopental into the epidural space. They were successful in handling the problem and the patient was not harmed. My comment concerns a statement made in the discussion of the problem. The authors say, "The lower pH (4.1) of the local anesthetic mixture would also retard thiopental absorption." I would like to ask the authors about the mechanism of this pH effect.

Offhand, I would have assumed it would work the other way around. Since thiopental is a weak acid with a pK of 7.6, any acidification of the thiopental solution should increase the unionized fraction of the thiopental while decreasing the ionized fraction. This would mean that, with falling pH, the amount of unionized, ie, absorbable and diffusible, thiopental would increase as pH falls. This mechanism should, if my assumptions are correct, be particularly useful if the pH could be lowered in the compartment that contains the thiopental but not in the compartment which is to receive the thiopental.

I am also assuming that pH would not actually fall to 4.1 but would change in a range in which a shift from ionized to unionized would still be of clinical significance.

* * *

To the Editor:

In considering Dr. Gravenstein's question, we have found it necessary to distinguish between blood solubility and membrane diffusibility of thiopental. At physiologic pH in blood, thiopental solubility is limited to 1.2 mg/ml. To increase solubility, the pH is raised to 10.6 with sodium carbonate, to permit concentrations of 20 mg/ml and higher. Decreasing the pH of thiopental solutions after injection into the bloodstream can be shown to favor precipitation, and crystals can be filtered from blood collected proximally.[1] Thus, we sought to hinder absorption of the thiobarbiturate by lowering its pH with local anesthetic solution, causing precipitation of acid thiopental. In vitro, an equal mixture of 2% thiopental and bupivacaine-lidocaine, as described in our case report, would achieve a pH of 8.8, with visible precipitation of thiobarbiturate.

Dr. Gravenstein suggests that the diffusion of thiopental across membranes would be facilitated by acidification, rather than impeded. We would have to agree that absorption of thiopental would be better at lower pH, with progressive increases in the unionized fraction. It was our thought that less thiopental would be available for absorption after precipitation of the drug. Perhaps a better choice of wording would have been "to promote thiopental precipitation." Whether this precipitation would significantly retard the rise of serum thiopental concentrations, given the increased absorption to be expected, would remain to be determined. We appreciate Dr. Gravenstein's correction.

To the Editor:

In your issue for May-June 1975, there was yet another article on awake intubation,[1] the authors inflicting this trauma on no less than 37% of their patients, noting en passant that anesthetists pay only lip service to this technic.

As one who does less than pay lip service to this technic, I would like through your columns to explain why. As a resident, I spent considerable time reading, from the experts, the pros and cons of the head-up, the head-down, and the flat positions, with or without cricoid pressure, with or without topical analgesia, etc. The recommendations are often dogmatic and often conflicting.

In the interests of simplicity, I opted for the Trendelenburg position, and since that decision, in 8 years of anesthesia practice, I have never had an aspiration, despite numerous inductions--both intravenous and gaseous--of patients with full stomachs, intestinal obstruction, and so on. With the patient induced in Trendelenburg, I have on many occasions seen copious amounts of fluid run harmlessly onto the floor and simultaneously inserted an endotracheal tube into a trachea as dry as a bone. The procedure is simple and requires no special equipment and is always available. The alternatives, as described numerous times previously, are meddlesome and traumatic both emotionally and physically for the patient, and do not provide a better standard of care.

To the Editor:

I have been following closely the "debate" on intermittent mandatory ventilation that has appeared in your Journal. There apparently is a side to this issue which could use some emphasis at this time. Successful weaning from mechanical ventilation requires careful monitoring for ultimate patient safety, with multiple T-tube trials. In a small community hospital such as I practice in, this may severely stress the available resources. IMV facilitates safe patient management in a number of ways:

1. Handling of the intubated airway is reduced, since weaning time is advanced by changing the machine settings and not by switching from machine to T-tube. This also means that if a patient tires at one setting, the machine setting can be altered simply and the patient safely returned to a different ventilatory level without risking accidental disconnection or contamination of the airway or trauma produced by manipulation of the tube.

2. Since spontaneous ventilation may persist, the patient is allowed to control his own Pa_{CO2} to some extent, thus avoiding easy passive hyperventilation to profound levels of alkalosis with associated CSF acid-base changes that may retard or complicate eventual independence from the ventilator. This is most important in patients with chronic lung disease.

3. Other problems such as "ventilatory-discoordination," accidental disconnection, and extreme requirements for sedation and/or paralysis are managed more effectively with IMV. Patients appear to be far more consistently in coordination with the machine at all settings than with other patterns of mechanical ventilation.

Most of our patients are elderly, with siginificant chronic lung disease. The almost universal use of IMV has made mechanical ventilation more efficient, easier to manage, safer, and has markedly increased ICU-personnel morale.

ANTIEMETIC EFFECT OF THC Oral delta-9-tetrahydrocannabinol (THC) was compared with a placebo as an antiemetic for nausea and vomiting following cancer chemotherapeutic drugs. Oral THC (10 mg/m^2) was an effective antiemetic in 14 of 20 courses while the placebo was ineffective in all instances. The lack of THC effect in some patients may be related to failure of gastrointestinal absorption. No patient vomited while experiencing a "high" from THC. Although somnolence often occurred with this THC dose, a significant curtailment of activities was infrequent. Toxicity (fear, panic, hallucinations) occurred in only two patients, both after three THC doses of 20 mg. *(Sallan SE, Zinberg NE, Frei E: Antiemetic effect of delta-9-tetrahydrocannabinol in patients receiving cancer chemotherapy. Effect of Mechanical Ventilation with End-Inspiratory Pause on Blood-Gas Exchange

SAMIR F. FULEIHAN, MD*
ROGER S. WILSON, MD†
HENNING PONTOPPIDAN, MD‡
Boston, Massachusetts§

The effects of end-inspiratory pause (EIP) on gas exchange were measured in 10 adult patients with acute respiratory insufficiency while maintained on mechanical ventilation. Four inspiratory patterns were studied with a constant tidal volume (10 to 15 ml/kg body weight), respiratory rate (9 to 12 breaths/min), F_{IO_2} (0.5) and end-expiratory pressure. Inspiratory flow rate ($\dot{V}_{insp}$) and EIP time were varied to produce a control pattern ($\dot{V}_{insp}$ = 60 L/min, EIP = 0), 2 EIP patterns of 0.6 and 1.2 seconds with a similar $\dot{V}_{insp}$ and a "slow" flow pattern ($\dot{V}_{insp}$ = 30 L/min) without EIP. The control pattern was applied before and after each study period.

Arterial oxygenation was unchanged with both EIP and "slow" flow patterns when compared to control. Dead-space ventilation (V_D/V_T) and P_{aCO_2} were significantly decreased ($p<0.01$) as EIP was increased from 0 to 1.2 seconds, but remained unchanged with slow inspiratory flow. Thus, EIP improved the efficiency of ventilation with no apparent improvement in oxygenation in patients with acute respiratory insufficiency.

FLOW and pressure patterns produced by various ventilators differ widely and have varying effects on the efficiency of gas exchange. End-inspiratory pause (EIP) is a ventilatory pattern characterized by a period of no-flow occurring at the end of inspiration. The inspired tidal volume is retained in the lungs for a finite period of time, resulting in a prolongation of "inspiration" without airway gas flow.[1]

Previous studies using lung models have shown that uneven distribution of ventilation resulting from regional differences in airway resistances may be improved by the addition of a no-flow interval at the end of inspiration.[2-4] In addition, studies in anesthetized animals have demonstrated an improved alveolar ventilation ($\dot{V}_A$) and ventilation to perfusion ratio ($\dot{V}_A/\dot{Q}$) when EIP is included in the pattern of ventilation.[5,6] The purpose of this study was to determine whether addition of EIP to a ventilatory pattern has any beneficial effect on blood-gas exchange in patients with acute respiratory insufficiency (ARI).

METHODS

Ten adult patients with ARI of varying etiology were studied at a time of stable respiratory and cardiovascular function. Salient anthropometric and medical details are summarized in tables 1 and 2.

All patients were studied in the semisitting position. Each had a cuffed endotracheal or tracheostomy tube with an airtight fit. Patients were ventilated mechanically and were well in phase with the ventilator cycling. One hour prior to the study, they were switched from the ventilator used clinically to a volume-preset, constant-flow generator* which incorporated a variable inspiratory hold time (0.2 to 2 sec.).

*Plateau compliance: described in text.

Four ventilatory patterns were studied while all the following were maintained constant: *tidal volume* (V_T = 10 to 15 ml/kg body weight), *respiratory rate* (9 to 12 breaths/min), *inspired O_2 concentration* (F_{IO_2} = 0.5) and *end-expiratory pressure* (EEP). In 4 patients (#3, 6, 8, 9), where positive end-expiratory pressure (PEEP) was used in clinical management, it was maintained at the same level during the study. *Inspiratory flow rate* ($\dot{V}_{insp}$) and *EIP time* were varied to produce a control pattern ($\dot{V}_{insp}$ = 60 L/min, EIP = 0), 2 EIP patterns of 0.6 and 1.2 seconds ($EIP_{0.6}$ and $EIP_{1.2}$) with a similar $\dot{V}_{insp}$ and a "slow" flow pattern ($\dot{V}_{insp}$ = 30 L/min) without EIP (table 3). The control pattern was interspaced before and after each study period. Each pattern was maintained for a period of 45 to 60 minutes, during which the following hemodynamic and ventilatory measurements were made:

Vital Signs.—Heart rate and rhythm were recorded continuously; blood pressure and central venous pressure (CVP) were determined at 5-minute intervals, and urine output was measured hourly.

$AaDO_2^{0.5}$: alveolar-arterial oxygen difference measured at F_{IO_2} = 0.5.
ARI: acute respiratory insufficiency.
C_T: total compliance.
CVP: central venous pressure.
EEP: end-expiratory pressure.
EIP: end-inspiratory pause.
EIPP: end-inspiratory plateau pressure.
F_{ECO_2}: mixed expired CO_2 concentration.
F_{IO_2}: inspired O_2 concentration.
FRC: functional residual capacity.
I/E: inspiratory:expiratory ratio.
IP: Inspiratory pressure.
MAP: mean airway pressure.
P_B: atmospheric pressure.
P_{ECO_2}: mixed expired CO_2 tension.
PEEP: positive end-expiratory pressure.
$P_{H_2O}T$: water vapor pressure at body temperature (T).
PIP: peak inspiratory pressure.
Q_S/Q_T: intrapulmonary right-to-left shunt (expressed as percentage of cardiac output).
RR: respiratory rate.
$\dot{V}_A$: alveolar ventilation.
$\dot{V}_A/\dot{Q}$: ventilation:perfusion ratio.
$\dot{V}CO_2$: carbon dioxide production.
V_{comp}: compressible volume.
$V_D$app: dead-space volume of mechanical apparatus.
V_Dm: measured dead-space volume.
$V_D$phys: physiologic dead-space volume.
V_D/V_T: dead-space:tidal-volume ratio.
$\dot{V}_{insp}$: inspiratory flow rate.
V_T: tidal volume.

Airway Flow and Pressure; Tidal Volume.—Airway gas flow was measured with a Fleisch pneumotachograph placed between the ventilator tubing and the endotracheal or tracheostomy tube. The flow signal was integrated electronically (Hewlett-Packard Respiratory Preamplifier—Model 350-5000) to measure inspired and expired gas volume. Airway pressure was measured with an appropriate pressure transducer (Hewlett-Packard 270 with 350-1100 Carrier Preamplifier) placed immediately proximal to the endotracheal tube. Airway pressure, flow, and volume were recorded simultaneously on a multichannel recorder.*

Characteristic flow and pressure configurations for each pattern are shown in figure 1. As EIP was instituted, peak inspiratory pressure (PIP) fell to a plateau level, referred to as the plateau pressure or end-inspiratory plateau pressure (EIPP). Inspiratory to expiratory (I/E) time ratio was determined from the chart record of the inspiratory-expiratory flow rates. The zero flow period (EIP) was considered to be part of the inspiratory time in the calculation of the I/E ratio.

Compliance.—Total compliance (C_T) was calculated at end of inspiration in the control and "slow" flow patterns and at end of the zero flow period in both EIP patterns. Due to the different inspiratory flow rates and the addition of EIP to certain patterns, IP varied; thus, the compliance values obtained were differentiated into dynamic, effective, and plateau compliances (see Appendix).

Arterial Blood Gases.—At the end of each study period, arterial P_{O_2}, P_{CO_2}, and pH values were determined with appropriate electrodes. The alveolar-arterial O_2 tension difference on 50% O_2 ($AaDO_2^{0.5}$) was calculated using the alveolar air equation[7] (see Appendix).

*Sanborn System, #964-1100.

Dead-Space Ventilation.—The physiologic dead-space to tidal-volume ratio (V_D/V_T) was determined by the Enghoff modification of the Bohr equation. Appropriate corrections for compressible volume (V_{comp}) and apparatus dead space ($V_D$app) were included and are shown in the appendix. Carbon dioxide production ($\dot{V}CO_2$) was determined during each study period.

Cardiac Output was measured in duplicate by the dye-dilution technic during the final minutes of the 2nd control period and during the $EIP_{1.2}$ pattern.

Functional Residual Capacity (FRC) was measured in 5 patients using the standard helium dilution technic.

Statistical analysis of each study pattern and preceding control was carried out using Student's *t*-test paired data, to determine significant differences in $AaDO_2^{0.5}$, V_D/V_T, $Paco_2$, $F\bar{E}co_2$, $\dot{V}co_2$, and cardiac output. Values were considered significant at the $p<0.05$ level.

RESULTS

Mean values for $AaDO_2^{0.5}$, $Paco_2$, V_D/V_T, $F\bar{E}co_2$, and $\dot{V}co_2$ during each ventilation period are shown in table 4. Results during the 4 control periods were quite similar, such that the initial control condition was always reestablished following each study pattern. The effect of each pattern on gas exchange was evaluated by comparing it with the preceding control. No appreciable changes were observed in heart rate, blood pressure, CVP, or urine output. Oxygenation ($AaDO_2^{0.5}$) remained unchanged with EIP and with "slow" flow patterns when compared with control values. Efficiency of ventilation improved with institution of EIP (fig 2). With $EIP_{0.6}$ mean V_D/V_T decreased by 9.6% and mean $Paco_2$ by 5.1%. $EIP_{1.2}$ produced a further decrease in mean V_D/V_T (19.6%) and in mean $Paco_2$ (9.7%). The "slow" flow pattern failed to improve the distribution of ventilation, as evidenced by lack of changes in either V_D/V_T or $Paco_2$. Carbon dioxide production and $F\bar{E}co_2$ (corrected for compressible volume) were not significantly changed during each of the different study patterns when compared with the preceding control. Mean cardiac output decreased by 10% with $EIP_{1.2}$ (range −23% to +2.3%).

Mean airway pressure (MAP) increased with the institution of EIP and with the "slow" flow pattern, due to prolongation of the inspiratory period (table 5); MAP was

*Represents mean values of the 4 control periods.

highest with $EIP_{1.2}$ and decreased in magnitude in the following order: $EIP_{1.2}$ > "slow" flow > $EIP_{0.6}$ >, control. Inspiratory:expiratory ratio was highest with both "slow" flow and $EIP_{1.2}$ patterns (table 5). The similarity of the mean values for I/E in the latter 2 patterns is purely coincidental. Analysis of all individual samples showed no correlation between either V_D/V_T and MAP or V_D/V_T and I/E. When "slow" flow samples were excluded, restricting the analysis to the control and the EIP patterns, a negative correlation ($r = -0.51$, $p<0.05$) was found between V_D/V_T and I/E. This implies that as I/E is prolonged with the addition of EIP (but not with "slow" flow) V_D/V_T decreases (fig 3).

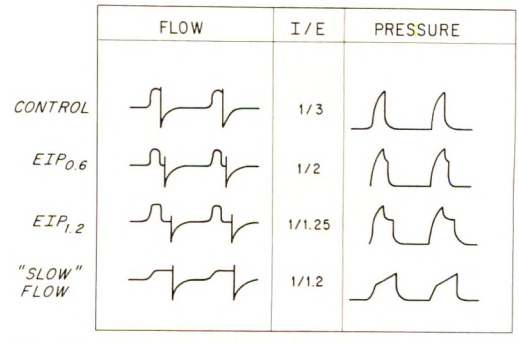

FIG 1. Airway flow, inspiratory-expiratory (I/E) time ratio, and airway pressure during ventilatory patterns.

DISCUSSION

The major findings of this study were: (1) V_D/V_T and $Paco_2$ were decreased in proportion to the duration of EIP; (2) EIP did not alter the efficiency of arterial oxygenation despite an improvement in alveolar ventilation; (3) "slow" inspiratory flow failed to change either dead-space ventilation or efficiency of oxygenation.

EIP and Hemodynamics.—The addition of EIP to ventilatory patterns prolongs I/E, sustains inspiratory pressure, and results in a higher MAP (fig 1 and table 5). An increase in mean intrathoracic pressure has been shown to impede venous return, which in the absence of compensatory mechanisms would be expected to produce a decrease in cardiac output.[8] Furthermore, sustained lung distention with increased alveolar pressure and subsequently higher transpulmonary pressure would elevate pulmonary vascular resistance, which in turn may contribute to the fall in cardiac output.[9,10] Studies in anesthetized dogs with normal lungs demonstrated a decrease in cardiac output and stroke volume with the addition of EIP.[6,9] Our results are in agreement with the preceding data. Nevertheless, despite the small decrease in cardiac output with $EIP_{1.2}$, there were no demonstrable effects on recorded vital signs, including blood pressure, heart rate, and urine output.

EIP and Oxygenation.—Previous studies with healthy dogs under general anesthesia have shown that the addition of EIP to mechanical ventilation increased room air Pao_2 and decreased calculated pulmonary shunt.[6] In dogs[11] with oleic acid-induced pulmonary edema, the addition of EIP to the ventilatory pattern had no beneficial effect on $AaDO_2$[1.0]. However, Pao_2 was significantly improved when PEEP instead of EIP was applied at a similar level of MAP.

In view of the previously suggested improvement in both alveolar ventilation and $\dot{V}_A/\dot{Q}$ by EIP, Cheney[11] postulated that the expected increase in oxygenation may have been masked in the experiment cited above because the dogs were being ventilated with

100% O_2. Patients in our study were ventilated with 50% O_2, and despite improved alveolar ventilation with EIP, there was no significant effect on oxygenation. The latter may be partially accounted for by the decrease in cardiac output, but even in patients whose cardiac output did not decrease, no improvement in oxygenation was noted. Cardiac output and $\dot{V}_A$ are not the sole determinants of Pao_2, which may be affected by the presence of pulmonary shunts and by whatever effect EIP might have upon the redistribution of cardiac output through the pulmonary vasculature. The latter phenomenon would probably affect $\dot{V}_A/\dot{Q}$, and this would require further documentation. We do not postulate that in a certain region of the lung where $\dot{V}_A$ improved following the addition of EIP, an expected regional improvement in O_2 content would occur even though this may not be reflected in the peripheral Pao_2.

EIP and Efficiency of Ventilation.—The nonhomogeneous properties of the diseased lung, for example, regional differences in compliance and airway resistance, result in uneven distribution of ventilation and thus interfere with gas exchange.[12] The Engström respirator has been designed to compensate for changes in lung mechanics, ensuring thus a most nearly equal intrapulmonary gas distribution even in the presence of unequal resistance factors.[13] Such an equilibration takes place during the static phase, when the respirator gas flow is essentially zero. At this stage, the excess volume which filled the lung was found to correspond to the available compressible volume from the respirator.[2]

In a dog model with mechanically induced unilateral bronchial obstruction, the static phase pattern of the Engström ventilator allowed for redistribution of inspired volume from nonobstructed to obstructed lung compartments.[14] Recent studies on lung models with regional differences in airway resistance revealed that EIP resulted in optimal distribution of ventilation regardless of flow rates of patterns utilized.[3,4] In a homogeneous lung model, alveolar dead space decreased as EIP was increased,[15] and in anesthetized dogs, the improvement in $\dot{V}_A$ with the institution of EIP was found to be directly proportional to the duration of added EIP.[5]

No such data have yet been collected in patients with acute respiratory disease. Our study reveals that in the latter group as well, EIP shows the same trend as was seen in lung models and experimental animals; efficiency of ventilation is improved as seen by a decreased V_D/V_T and $Paco_2$, the decrease being in proportion to the duration of EIP (fig 2).

Improved alveolar ventilation with EIP has been suggested to occur through two main mechanisms:[5] first, as in breathholding, by allowing more time for exposure of an inspired breath and therefore more unloading of CO_2 into alveoli. Calculated $V_D$phys decreases during breathholding,[16] and the effect of delaying expiration results in a higher alveolar CO_2 content than if expiration were not delayed.[15] Second, by recruitment of poorly ventilated alveoli in the presence of varying airway obstruction

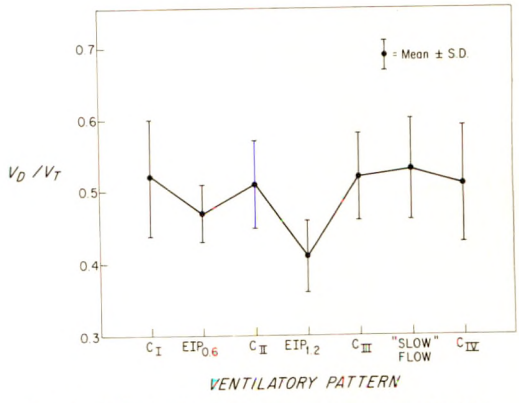

FIG 2. Effect of ventilatory pattern on V_D/V_T.

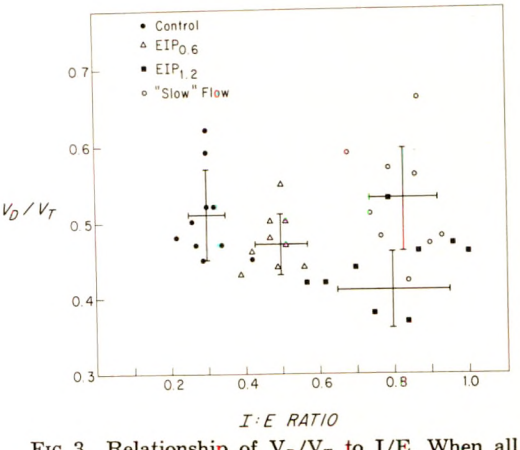

FIG 3. Relationship of V_D/V_T to I/E. When all ventilatory patterns were included, no correlation was found between V_D/V_T and I/E ($r = -0.71$). When "slow" flow samples were excluded, a negative correlation ($r = -0.51$, $p<0.05$) was found between V_D/V_T and I/E, implying a decrease in V_D/V_T as I/E is prolonged with the addition of EIP.

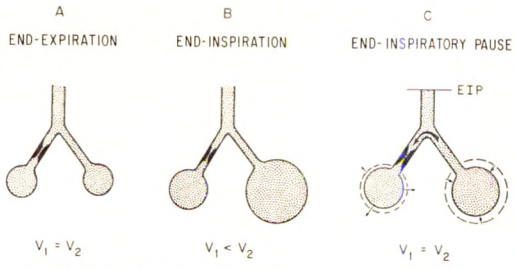

FIG 4. The effect of EIP on the distribution of ventilation in lung compartments with different airway resistances. Assuming 2 lung compartments (V_1 and V_2) with similar compliance and blood flow and an increased airway resistance in V_1 (A), then, during inspiration, the fast-filling compartment (V_2) receives the bulk of the insufflated volume (B). With EIP (C), redistribution of ventilation occurs from the fast-filling compartment (V_2) into the slow-filling compartment (V_1).

resulting in an increased effective diffusing surface and decreased $\dot{V}_A/\dot{Q}$ imbalance,[5] a mechanism illustrated in figure 4:

Assuming two lung compartments with similar compliance, equal blood flow and different airway resistances, if air is insufflated at a fast flow rate, the fast-filling compartment, that is the one with least airway resistance, would receive the bulk of the volume, resulting in an overblown compartment. This mechanism has been suggested by Norlander[2] to compress neighboring lung compartments with subsequent decrease in their compliance. If expiration is allowed to proceed immediately at the end of inspiration, no time would be provided for gas redistribution, resulting in unequal ventilation and $\dot{V}_A/\dot{Q}$ imbalance. If instead, EIP is instituted at the end of inspiration, the latter would delay expiration and would provide time for equal redistribution of ventilation and therefore improved $\dot{V}_A$ and $\dot{V}_A/\dot{Q}$ imbalance.

V_D/V_T, MAP, and I/E.—In patients without pulmonary disease, ventilation was found to be more efficient during intermittent positive-pressure breathing using high mean airway pressure.[17] In our study, changes in V_D/V_T did not correlate with changes in MAP; this is in agreement with previous findings, where V_D/V_T did not vary with MAP so long as inspiration lasted more than 1 second.[18]

As I/E was prolonged with the addition of EIP, V_D/V_T decreased. The latter did not occur when I/E was prolonged by slowing the inspired flow rate (fig 3). This indicates that it is not merely I/E, but rather how inspiratory time is utilized, that seems to influence the efficiency of ventilation. Slowing the flow rate did not improve V_D/V_T in our studies, and this is in disagreement with findings in lung models where $\dot{V}_A$ to obstructed compartments was improved with a slow flow rate.[4] Also, previous studies with patients have shown that $V_D$phys and V_D/V_T increased as $\dot{V}_{insp}$ was increased above 25 L/min, but in the latter studies, no correction for compressible volume was done, which make the results difficult to evaluate.[19]

Use of EIP in Noncompliant Lungs.—In studies on lung models with regional differences in compliance, ventilation to the poorly compliant regions was not improved with changes in flow rate and flow pattern or with the addition of EIP.[4] Therefore, it was suggested that in poorly compliant lungs, it may be more advantageous to use a rapid inspiration with volume acceleration.[3] Our data do not provide a solution as to whether EIP would have an effect on the ventilation of poorly compliant lungs. However, in patient 8, where C_T was markedly decreased (table 2), there was a significant improvement in V_D/V_T with the institution of $EIP_{1.2}$.

We conclude that this study confirms that the addition of EIP to the inspiratory flow pattern in patients with ARI produces a definite improvement in alveolar ventilation and $V_D$phys, but has no demonstrable effect on efficiency of oxygenation. This may not be of practical significance in the short-term management of patients; however, the long-term effects of maintaining EIP may result in a beneficial effect on gas exchange and pulmonary mechanics, and may provide a more nearly optimal condition for lung repair in otherwise poorly ventilated alveoli. One practical value of EIP is that it allows easy measurement of plateau compliance, a reproducible value important in the assessment and follow-up of pulmonary function in critically ill patients.

APPENDIX

I. Total Compliance (C_T) = $\triangle V$ (ml) / $\triangle P$ (cm H_2O) = V_T (recorded by pneumotachography) / IP-EEP. End-inspiratory pressure coincided with peak inspiratory pressure in the control and "slow" flow patterns and with the "plateau pressure" in both EIP patterns (fig 1). C_T as measured in the control pattern represented dynamic compliance. In the "slow" flow pattern, the

latter was referred to as effective compliance, since duration of inspiration was 2.5 to 3.1 seconds as compared to 1.2 to 1.6 seconds in the control period. C_T measured in both EIP patterns was referred to as plateau compliance.

II. $AaDO_2 = P_{AO_2} - P_{aO_2}$, where $P_{AO_2} = P_{IO_2} - P_{ACO_2}\left(F_{IO_2} + \frac{1 - F_{IO_2}}{R}\right)$.

P_{ACO_2} was assumed to be equal to P_{aCO_2} and R (respiratory quotient) was assumed to be constant at a value of 0.8. This assumption introduces an element of uncertainty but is considered justified since the patients were investigated in a quasi-steady state.

III. V_D/V_T was calculated according to the standard formula:

$$V_D/V_T = \frac{P_{aCO_2} - P\bar{E}CO_2}{P_{aCO_2}} \text{ (corrected)}.$$

Expired gas was collected into a 60 L Douglas bag at the end of each ventilatory pattern during a 3-minute period. Expired gas volume was measured with a Tissot spirometer and corrected to BTPS. Mixed expired CO_2 concentration ($F\bar{E}CO_2$) was determined with an infrared CO_2 analyzer (Beckman Model LB-1) and $P\bar{E}CO_2$ was derived as follows: $P\bar{E}CO_2 = F\bar{E}CO_2 (P_B - P_{H_2O^T})$. $P\bar{E}CO_2$ was corrected for both the compressible volume of the ventilator tubing (3.5 ml/cm H_2O) and the effect of added apparatus dead space. To correct for compressible volume, end-inspiratory pressure was used in the same manner as described for the compliance measurements (appendix, I).

Based on previous physiologic considerations[20] that in the presence of unperfused alveoli, the increase in physiologic dead space is constantly smaller than the size of added apparatus dead space, the formula ($V_D phys = V_D m - 0.5\ V_D app$) seems more appropriate than the conventional $V_D phys = V_D m - V_D app$. The latter would actually result in an underestimation of physiologic dead space. A similar corrected value of $V_D phys$ may be approximated through the following equation:*

$$V_D/V_T = \frac{P_{aCO_2} - P\bar{E}CO_2\left(\frac{V_T}{V_T - V_{comp} - 0.5\ V_D app}\right)}{P_{aCO_2}}$$

NB: Because of some variation in the value of V_T measured with the Tissot spirometer or with the pneumotachograph, both values were used in calculating V_D/V_T. The difference in V_D/V_T calculated according to both methods was negligible (0 ± 0.02 at most). The reported figure is the average of both numbers.

IV. $\dot{V}CO_2 = V_T$ (measured with the Tissot spirometer and corrected for BTPS) $\times$ respiratory rate $\times F\bar{E}CO_2$.

*Our computation.

Guest Discussion

JOHN B. DOWNS, M.D.
Department of Anesthesiology
University of Florida
College of Medicine
Gainesville, Florida

The authors demonstrated increased efficiency of alveolar ventilation when an end-inspiratory pause (EIP) was added to the mechanical ventilatory pattern of patients with acute respiratory insufficiency. Based on this observation, it might seem desirable to introduce such a mechanical ventilatory pattern to the therapeutic regimen of patients with excessive CO_2 retention. However, positive pressure ventilation which will increase mean airway pressure, mean intrapleural pressure, and to a lesser extent left atrial pressure, may decrease diastolic filling of the left ventricle and cardiac output. Thus, EIP may exaggerate the adverse hemodynamic effects of mechanical ventilation.

The observed increase in alveolar ventilation following addition of EIP would be most beneficial for patients with hypercarbia. Such patients frequently have marked obstructive lung disease or severe hypovolemia and increased physiologic dead space. Unfortunately, the cardiovascular effects of EIP would be tolerated least by such patients. In most patients who require mechanical ventilator support, CO_2 elimination can be enhanced by a slight increase in tidal volume or ventilator rate. Since hypocarbia is more common than hypercarbia in patients receiving mechanical ventilatory therapy, addition of EIP may be desirable only in select cases.

Recently, other investigators[1] found plateau compliance to correlate positively with systemic O_2 transport and, therefore, recommended that plateau compliance be used as an indicator of pulmonary function in patients with acute pulmonary failure. The present authors' data do not support this premise. The $AaDO_2^{0.5}$ did not correlate negatively with plateau compliance, as might have been predicted (tables 2 and 4). Since cardiac output was reduced significantly following addition of EIP, there must have been a significant decrease in systemic O_2 transport. This implies that pulmonary mechanics and gas exchange should be evaluated independently in patients with acute respiratory insufficiency.

The authors are to be congratulated for providing reliable information obtained from well-controlled measurements in patients with respiratory insufficiency rather than in lung analogs, animals, or patients undergoing general anesthesia. As Dr. Bergman wrote,[2] "The lungs are composed, in part, of 300,000,000 alveoli together with extremely complex systems of conducting tubes for both gas and blood and are enclosed in a unique container. Their function cannot be studied by observing the inflation of two rubber bags at the end of a Y-piece."

Hopefully, manufacturers will await the results of pertinent investigations such as Dr. Fuleihan's prior to marketing expensive machines capable of providing multiple inspiratory and expiratory pressure-flow patterns which may or may not have clinical efficacy.

QUESTION: *I find the word "torr" used increasingly in place of mm Hg. What is the origin of this word, and is it an exact synonym for mm Hg?*

M.D., Illinois

ANSWER: "Torr" derives from the name of the inventor of the mercury barometer, Evangelista Torricelli, an Italian physicist-mathematician (1608-1647). Early Hg barometers were known as Torricelli tubes. Because "torr" is a more convenient term than mm Hg typographically, it has been widely accepted in scientific literature.

Strictly, 1 torr is 1 mm Hg pressure equal to $\frac{1}{760}$ of normal atmospheric pressure (1.316×10^{-3} atm), or the pressure necessary to support a column of mercury 1 mm high at 0° C and standard gravity.[1,2] Usage has made the term generally acceptable as a synonym for mm Hg at ambient or clinical temperatures, as well.

QUESTION: *What is the present status of intrathecal cold saline solution for intractable pain, primarily of adenocarcinoma?*

M.D., Kansas

ANSWER #1: Encouraging results with the use of intrathecal cold saline were reported not only by Collins and associates[1] but also more recently by Savitz and Malis.[2] Many clinicians, however, have not been able to duplicate the results obtained by these authors. A number of clinics, including our own, are now evaluating the use of intrathecal hypertonic saline (7.5 percent) for the relief of intractable pain, as described by Hitchcock.[3] Both these technics are attractive because relief of pain is achieved without producing sensory anesthesia. It should be noted, however, that the procedure is not without definite risks.

In a recent questionnaire circulated among neurosurgeons using the injection of hypertonic saline for debilitating pain syndromes, a small but significant morbidity was noted, of which the most common, paraplegia or quadraplegia, occurred in 0.05 percent of the total patient population (2000). Other significant morbidity consisted of paresis of one leg, myocardial infarction, and cerebrovascular accident. In summary, I think that the injection of intrathecal saline for the relief of intractable pain requires further clinical evaluation before its relative place vis-a-vis standard forms of treatment of intractable pain secondary to carcinoma (drug therapy, chordotomy, intrathecal alcohol) can be established.

Detroit, Michigan

ANSWER #2: The use of intrathecal cold saline has decreased in my practice for three reasons:

1. The belief that it was not the cold that was providing the pain relief but the hypertonicity of the solution.

2. My practice has changed in that I no longer see many battle casualties with causalgia.

3. The effectiveness in cancer patients is only temporary and has not been recommended by me in treatment of cancer pain.

I have used the method with moderate success in patients with post-herpetic neuralgia. Also I have used the technic in paraplegics and amputees with phantom pain and/or sympathetic reflex dystrophy.

At the time I was actively using the technic, other individuals were using hypertonic saline, that is, 5 and 10 percent solutions at room temperature, with comparable results.

The question is vague, in that I don't know the site of the cancer or the nature of the pain. If the pain is that of adenocarcinoma of the bowel, it would seem to me that a splanchnic plexus block would be more effective. Intrathecal cold saline is one of the means we consider in our course of pain therapy; however, as I mentioned above, our use of this technic has decreased.

QUESTION: *Do you have any experience with prolonged continuous epidural for postoperative patients in the treatment of pain? How long can you keep the catheters safely? What is your experience on fractional doses of antibiotics injected into the epidural catheter to keep it clean and sterile? Please furnish me with some references and literature about epidural antibiotics with prolonged catheterization.*

M.D., Maryland

ANSWER #1: Continuous epidural anesthesia for postoperative pain relief can be a useful substitute for narcotics in specific patients following abdominal surgery.[1-4] Several reports have documented this fact and those who advocate its frequent use can show that patients will maintain more normal pulmonary function,[5,6] recover faster,[2] and perhaps be more comfortable.[5] The limited popularity of this method of pain relief is undoubtedly related to the fact that it can be time consuming and usually demands the attention of the physician for repeated injections. The busy and beleaguered anesthesiologist would rather resort to the more common canon of parenteral narcotics for postoperative analgesia, with the pious conviction that the patient will do just as well.

In an effort to establish prolonged postoperative pain relief or chronic sympathetic block, I have left epidural catheters in place as long as a week. Others report as many as 10 days.[7] The tachyphylaxis which frequently develops following multiple injections of local anesthetics will very often limit the useful life of a continuous epidural to a much shorter time.[8] However, as long as the catheter fulfills the purpose for which it was put in place, I see no reason to remove it because of some arbitrary time factor.

The epidural abscess is a disastrous condition which can occur spontaneously, result from trauma,[9] or follow lumbar and caudal instrumentation. It does, however, seem to rank very low among the possible complications of epidural anesthesia. In one study aimed at looking into the potential for epidural infection, several cultures of catheter tips, solutions, and even the surrounding skin were found to be virtually free of bacteria.[7] The authors, however, were very scrupulous with methods of introducing the catheter and its protection after it was in place.

Based on these facts, I would question the wisdom or the need for a prophylactic treatment method such as injecting into an epidural catheter fractional doses of antibiotics, when the apparent incidence of infection is so low. Another consideration is the fact that the antibiotic itself might be harmful to the nerve root because of such factors as osmolarity, pH, or chemical toxicity. I know of no one who uses prophylactic antibiotics and I would personally have serious reservations about the need or the safety of such a practice.

ANSWER #2: To answer this important question, I will report on the use of continuous epidural analgesia for both postoperative pain and chronic pain states. For the purpose of description, these will be divided into two groups, the first consisting of 600 cases in which the epidural catheter was left in situ for a mean duration of 28 hours. The second group of 27 cases, being managed for various chronic pain states, will be further subdivided into short (7), medium (11), and long (6) periods. The mean duration of catheterization in these groups was, respectively, 2.5, 3.4, and 5.7 days. Three patients were blocked for 9, 11, and 18 days, respectively. These three cases represent an extreme application of this technic, which was an adjunct to concurrent hypno- and psychotherapy. They illustrate what may be a fundamental property of the epidural space, namely resistance to infection, presumably through the great vascularity contributed by the internal vertebral venous plexus together with its segmental connections, which has been adequately described by Batson.[1]

In addition, there is good evidence that local anesthetics are, if not bactericidal, bacteriostatic. A good account of the antimicrobial activity of lidocaine and procaine is given by Schmidt and Rosenkranz,[2] who testify to the broad spectrum of bactericidal activity of these two local anesthetics. Earlier literature by Murphy and his colleagues[3] describes the toxic effects of 0.5 percent solution of tetracaine on Pseudomonas organisms. These two papers suggest that this property may be shared by other anilide types of local anesthetics currently in use.

I have no experience in the use of fractional doses of antibiotics, and the literature is singularly void of any references in this regard. However, there seems little argument in favor of prophylactic administration of epidural antibiotics. In fact, on first principles, even in the presence of an infection, it would appear more appropriate to give parenteral antibiotics. Also, one should remember that some antibiotics, notably penicillin and streptomycin, can give rise to convulsions when applied to the spinal theca. An account by Bordbar and Beheshti[4] of two such cases appeared recently, and reference to this effect is also made by Goodman and Gilman.[5]

I advocate the use of long-term epidural block for the control of pain either in the postoperative period or in pain states, provided an aseptic technic is followed during each reinjection and provided modern inert (nylon or Teflon) catheters are used, with or without a micropore filter; then there is no argument in favor of using epidural antibiotics.

QUESTION: *The Joint Commission on Hospital Accreditation demands that the humidity of the operating room be kept at 55%. We realize this was done to reduce the explosion hazards where explosive anesthetic agents were in use. In our operating rooms, we do not use explosive anesthetics or combustible prepping solutions (spray tc of benzoin being the only flammable agent in use). We find it difficult to maintain 55% humidity and twice have been cited by the Joint Commission for this.*

We see no need for 55% humidity, but only 30 to 35% humidity for comfort control. This seems to be an archaic rule that is not necessary where explosive agents are not in use, but we cannot convince the Joint Commission.

Are we wrong, or should the Joint Commission accept 30 to 35% humidity where explosive anesthetics are not in use and rooms are air conditioned and conductive floors exist?

M.D., Ohio

ANSWER: At a meeting of the ASA Committee on Flammable Hazards and Electrical Equipment, May 14, 1975, the consensus of the Committee was that 50% humidity was still desirable for: (1) control of static electricity (startle reaction); (2) comfort of personnel; and (3) to facilitate the control of airborne bacteria. This requirement was felt to be important for nonflammable as well as flammable anesthetizing locations.

Currently, the JCAH recommends in the Accreditation Manual for Hospitals (1970, updated 1973) that NFPA 56A 1968 should be used as a guide in establishing controls to minimize the hazards of fire and explosion in areas where flammable anesthetics are used; also, that NFPA Standards should be used to develop regulations relative to anesthetic safety (see JCAH Manual, pp 62 and 85). NFPA 56A 1973 is the latest edition of the Standard for the Use of Inhalation Anesthetics and still states that "a relative humidity of not less than 50% at a temperature range of 70° ± 5° F, shall be maintained in anesthetizing locations, both flammable and nonflammable."

The NFPA Sectional Committee on Anesthetizing Agents, which is responsible for the NFPA 56A Standard, met in Cleveland on July 11, 1975, and agreed to review this requirement at their next meeting.

AWAKE DURING OPERATION Awareness during anesthesia and operation may result in a traumatic neurotic syndrome. The authors describe such a syndrome in six patients characterized by 1) recurrent nightmares, 2) irritability, 3) a preoccupation with death, and 4) reluctance to describe symptoms to physicians for fear they would be misinterpreted. In all six cases a direct explanation to the patient that they indeed were "awake" during the operation served as a dramatic cure. The incidence of such occurrences may be underestimated due to patient reluctance to discuss their symptoms. *(Blacher RS: On awakening paralyzed during surgery. A syndrome of traumatic neurosis. JAMA 234:67-68, 1975)*

Hemodynamic Effects of Isoflurane and Halothane in Patients with Coronary Artery Disease

JAMES E. MALLOW, M D *
ROGER D. WHITE, M D †
ROY F. CUCCHIARA, M D †
SAIT TARHAN, M D †
Rochester, Minnesota‖

In 12 patients undergoing saphenous vein coronary artery bypass operations, cardiovascular hemodynamics were studied in the awake state (control) and during anesthesia with isoflurane (inspired concentration, 1.24%, 7 patients) or with halothane (inspired concentration, 0.77%, 5 patients). Isoflurane anesthesia was accompanied by decreases of 19% in the cardiac index ($\dot{Q}$), 19% in mean arterial pressure ($\overline{AP}$), and 16% in heart rate (HR). Only the change in $\overline{AP}$ was statistically significant. Halothane anesthesia was accompanied by decreases in $\dot{Q}$ (28%), $\overline{AP}$ (22%), and HR (10%). The changes in $\dot{Q}$ and $\overline{AP}$ were significant. HR did not change significantly following the induction of anesthesia with either agent. The decrease in $\overline{AP}$ was similar with both agents, and, in this regard, neither agent was clearly superior for patients with occlusive coronary artery disease.

RECENT studies have suggested several advantages of isoflurane anesthesia as compared with halothane anesthesia in man. These have included the absence of sensitization of myocardium to exogenously administered epinephrine;[1] minimal metabolism in man;[2] lower blood-gas partition coefficient, leading to more rapid induction and emergence;[3] and better maintenance of cardiac output.[4]

The last of these reported advantages has not been documented for patients with limited cardiac function. Accordingly, we designed a clinical study of patients with coronary artery disease (CAD), to determine whether isoflurane anesthesia would maintain cardiovascular hemodynamics better than halothane anesthesia at equivalent minimum alveolar concentrations (MAC).¶ Patients were selected at random and anesthetized with either isoflurane or halothane in O_2. Cardiovascular hemodynamics were measured in the awake and anesthetized states with each agent, and the hemodynamic changes produced by the two anesthetics were compared.

METHODS

The study group comprised 12 patients without clinical evidence of pulmonary disease, scheduled for saphenous vein bypass grafting for CAD. All patients were New York Heart Association class III and were premedicated with diazepam (10 mg) and morphine sulfate (6 to 8 mg) IM 1 hour before study. Seven patients were anesthetized with isoflurane [3 single-vessel (LAD), 3 double-vessel, 1 triple-vessel disease, 0 ventricular dyskinesia] and 5 with halothane [1 single-vessel (LAD), 2 double vessel, 2 triple-vessel disease, 0 ventricular dyskinesia]. In the isoflurane group, the average age was 54 years and surface area was

¶In man, the MAC of isoflurane in O_2 is $\pm 1.24\%$[3] and of halothane in O_2 $\pm 0.77\%$.[5]

1.99 sq m; in the halothane group, 53 years and 1.92 sq m. Informed consent was obtained from each patient the day before operation.

Prior to induction of anesthesia, standard limb leads for ECG monitoring were attached and a CVP catheter (30-cm, 16 gauge) was inserted percutaneously into the right internal jugular vein, localized in the right atrium by ECG,[6] and connected to a Statham 23-BB strain gauge. A 75-cm Teflon catheter was placed in the descending aorta via the left femoral artery (Seldinger technique[7]) and connected to a 23-D Statham strain gauge. A thermistor probe was placed in the right axilla. Right atrial (P_{RA}) and systemic arterial pressures ($\overline{AP}$) were monitored continuously.

Cardiac output ($\dot{Q}$) was determined by the dye-dilution technique.[8] Indocyanine green* (5 mg/ml) was injected into the right atrium, arterial blood was withdrawn from the descending aorta by a Harvard pump through a Gilson cuvette (model DTL) at 10 ml/min, and the dye curve was recorded simultaneously with the ECG on a Century oscillograph recorder (model 470).

Blood gases were analyzed by withdrawing arterial blood anaerobically from the descending aorta into 5-ml plastic syringes, the dead spaces of which were filled with heparin (1000 U/ml). The syringes were immediately sealed and placed in an ice bath. Pao_2, $Paco_2$, PH, and hemoglobin (hgb) were determined for each sample (37° C; Radiometer electrodes model PHM 27 and Co-Oximeter IL model 182) within 10 minutes of blood withdrawal. Standard bicarbonate was calculated with a Severinghaus slide rule.

After placement of all sensors, the awake subjects inspired 100% O_2 (nonrebreathing system) for 10 minutes. Measurements were then obtained in the following sequence:

1. arterial blood sample
2. axillary temperature
3. $\overline{AP}$ and P_{RA} measured during three respiratory cycles
4. $\dot{Q}$ followed by repeat determinations of $\overline{AP}$ and P_{RA}, axillary temperature, and arterial blood sample.

The ECG was recorded continuously. This sequence was repeated until the results of two cardiac outputs in sequence varied by less than 10%.

Induction was with either isoflurane (1.5 to 5%) or halothane (1 to 2.5%) in O_2. Endotracheal intubation with a soft-cuffed endotracheal tube was facilitated with succinylcholine (100 mg IV). For maintenance, a constant inspired concentration of isoflurane (1.24%) or halothane (0.77%) in O_2 was administered from a calibrated Fluotec® Mark II vaporizer. Each patient was mechanically ventilated at a respiratory frequency of 16/min and a tidal volume of 0.47 to 0.52 L. Tidal volume was delivered via an Engstrom Respiratory System (model ER311) with peak airway pressures of 12 to 15 cm H_2O.

After 15 minutes at the respective constant inspired concentrations and prior to the scheduled surgical procedure, all measurements were repeated in the same sequence. Blood lost through sampling (average, 100 ml) was not replaced.

Statistical comparisons of the differences between the two groups of patients were made using Hotelling's *t*-squared test (unpaired data), and comparisons of the differences between the awake and anesthetized states were made by Student's *t*-test (paired data). Comparisons were accepted as significantly different when $p<0.05$.

RESULTS

Values relating to the awake state for the isoflurane and halothane groups did not differ significantly (table). In addition, the values for hgb, standard bicarbonate, and body temperature were 14.9 gm/dl, 23.3 mEq/L, and 35.5° C, respectively, for the isoflurane group and 15.6 gm/dl, 24.6 mEq/L, and 36° C, respectively, for the halothane group. These values did not change significantly after induction of anesthesia.

Induction with isoflurane was associated with a significant change in systemic $\overline{AP}$, $Paco_2$, and pH (table). The decrease in $\overline{AP}$ was not associated with a significant decrease in either $\dot{Q}$ or systemic vascular resistance (SVR). $Paco_2$ decreased and pH increased by the same degree, due to mild hyperventilation in both groups. Induction of anesthesia with halothane was accompanied by a significant decrease of $\overline{AP}$, $\dot{Q}$, stroke volume index (SVI), and $Paco_2$ (table). The decrease in $\overline{AP}$ was paralleled

TABLE 1
Comparisons of Hemodynamic and Respiratory Variables in Waking State and in Anesthesia With Isoflurane and Halothane

Variable	Isoflurane (N = 7)		Halothane (N = 5)	
	Awake Mean ± SE	Isoflurane (inspired concentration, 1.24%) Mean ± SE	Awake Mean ± SE	Halothane (inspired concentration, 0.77%) Mean ± SE
Cardiac index (liter/min/m^2)	2.31 ± 0.27	2.03 ± 0.28	2.94 ± 0.32	2.13 ± 0.29*
Stroke index (ml/m^2)	35 ± 3	31 ± 3	39 ± 1	31 ± 1*
Heart rate (beats/min)	71 ± 12	60 ± 4	75 ± 6	68 ± 8
Right atrial pressure (mm Hg)	6.7 ± 1.2	8.4 ± 0.7	5.5 ± 0.7	6.5 ± 1.2
Mean arterial pressure (mm Hg)	97 ± 4	79 ± 5*	96 ± 3	75 ± 3*
Systemic vascular resistance (dyne-sec/cm^{-5})	1686 ± 184	1678 ± 224	1374 ± 160	1414 ± 120
Pa_{O_2} (mm Hg)	421 ± 18	384 ± 23	483 ± 16	477 ± 22
Pa_{CO_2} (mm Hg)	41 ± 1	35 ± 2*	40 ± 1	33 ± 3*
pH	7.37 ± 0.06	7.41 ± 0.02*	7.39 ± 0.01	7.46 ± 0.02*

*Significantly different from value for waking state ($p < 0.05$).

by a decrease in $\dot{Q}$ and SVI; SVR did not change.

The decrease in $\overline{AP}$ from the awake to the anesthetized state in the isoflurane groups was not significantly different from the decrease measured in the halothane group (table).

Because of the relatively small number of patients studied and the wide individual variation in values for $\dot{Q}$, no significant difference in $\dot{Q}$ between the halothane and isoflurane groups was achieved (unpaired *t*-test), even though, as compared to their respective controls, a significant decrease occurred only in the halothane group (paired *t*-test).

HR did not change significantly from the control to the anesthetized state in either group, nor was there a significant difference in HR associated with isoflurane as compared to halothane.

DISCUSSION

A comparison between the cardiovascular effect of isoflurane and halothane anesthesia might be altered by three factors: (1) differences in $Paco_2$ and mechanical ventilation; (2) differences in MAC equivalents of isoflurane and halothane; (3) differences in the cardiovascular effects of isoflurane.

We consider it unlikely that the hemodynamic effects on these two groups can be accounted for by ventilatory differences, because respiratory frequency, tidal volume, peak airway pressure, and hypocapnia were of the same order for both groups.

The difference in MAC equivalents also seems unlikely as an explanation. Measurements were obtained in the anesthetized state after the patients had received a constant inspiratory concentration of isoflurane or halothane in O_2 for 15 minutes, preceded by induction of anesthesia with isoflurane (1.5 to 3.5%) and halothane (1 to 2.5%) for 5 minutes. Although the alveolar partial pressure of isoflurane may be expected to have increased at a faster rate than that of halothane when administered at a constant inspiratory concentration, we assume that MAC equivalents of isoflurane and halothane existed at the time the measurements were obtained. This assumption is supported by the data published by Cromwell's group[3] and by Rehder and colleagues.[9]

Rehder determined the ratio of expired to inspired halothane (F_{EHa}/F_{IHa}) in man to be 0.55, 0.69, and 0.75 after 15, 30, and 75 minutes, respectively, of exposure to a constant inspired halothane concentration, while Cromwell reported the ratio of expired to inspired isoflurane (F_{EI}/F_{II}) in man to be 0.62, 0.7, and 0.73 after 16, 32, and 64 minutes, respectively, of exposure to a constant inspired concentration. As the F_{EHa}/F_{IHa} and the F_{EI}/F_{II} are equal at 30 and 32 minutes, we believe that MAC equivalents of halothane and isoflurane were

nearly equal at the end of 20 minutes and that, therefore, a comparison of two agents is valid.

HR did not increase under isoflurane anesthesia in our patients, in contrast to the data published by Stevens and associates.[4] Similarly, no increase in HR (5 volunteers anesthetized with inspired isoflurane concentrations of 1 and 2%) from the awake to the anesthetized state was reported by Rehder in a later study.[10]

Patients with CAD, particularly those in whom the stenotic lesions of the coronary arteries are of fixed diameter, require careful management during general anesthesia to prevent acute myocardial ischemia. Ischemia occurs when the myocardial O_2 consumption ($M\dot{V}o_2$) exceeds the supply of O_2 delivered to the myocardium via the coronary arteries. A partially occluded coronary artery is associated with a pressure gradient across the stenotic area and with maximal dilation of the coronary artery distally.[11]

Under these conditions, coronary artery blood flow distal to the stenosis would be dependent primarily on aortic diastolic pressure;[12] and hence coronary blood flow then becomes essentially pressure-dependent. In patients with occlusive CAD, there is apparently an optimal aortic pressure[13] above or below which the balance between myocardial O_2 supply and demand is upset and acute myocardial ischemia results. The intraoperative development of acute myocardial ischemia secondary to hypotension without a proportionate reduction in $M\dot{V}o_2$ is manifested on the ECG by displacement of the ST segment.

In both of our groups, $\overline{AP}$ decreased significantly; the decrease with isoflurane anesthesia was not significantly different from that with halothane anesthesia, and no ST-segment deviation was observed in either group of patients. We assume, therefore, that $M\dot{V}o_2$ was appropriately decreased and that the optimum pressure range was maintained similarly by each agent, or that both of these were operative.

Our studies suggest (1) that HR did not change significantly following the induction of isoflurane or halothane anesthesia; (2) that, although cardiac output decreased significantly only after the induction of halothane anesthesia, we are unable to conclude that cardiac output was better maintained by isoflurane than halothane anesthesia—because of the small group of patients studied, the wide variation in cardiac output, and the higher cardiac output in the awake halothane group of patients; (3) that $\overline{AP}$ decreases similarly during both isoflurane and halothane anesthesia and, in this regard, neither agent is clearly superior for patients with coronary artery disease.

Editors share the belief that medical writing is capable of vast improvement. This article is one of a series of personal communications from Charles G. Roland, M.D., former Senior Editor of JAMA, to John T. Martin, M.D., Associate Editor of Anesthesia & Analgesia . . . Current Researches. Dr. Roland is Chairman, Department of Biomedical Communications, Mayo Clinic, Rochester, Minnesota 55901.

Thoughts About Medical Writing

XXXIII. Parallelism is a Virtue

Dear Tom:

In interpreting the written word, the brain can sort through remarkable jumbles. It *can*. But the brain works more efficiently—i.e., understands more quickly and more completely—when thoughts are expressed clearly. One powerful tool that helps the writer to communicate clearly is parallelism.

I would define parallelism in writing as that condition in which entities that complement each other are verbalized in such a way that their relationship is properly emphasized. That abstract definition may itself defy understanding, so let me give some concrete examples.

This sentence was part of a recent journal article: "The special clamp and other methods have been used." What's wrong here? The reader must, after reading "other methods," go back to "clamp" and satisfy himself that the author probably has been merely careless in saying that a clamp is a method. Obviously, a clamp is a concrete thing, whereas methods are abstractions. Careful readers, readers who are striving to understand, probably make computations like this in nanoseconds and don't realize they are making them. But the brain must make an unnecessary reversal nonetheless. In this case, the author would have saved the step by writing: "The special clamp and other instruments have been used." The clamp is an instrument. The appropriate parallelism has been introduced.

Longer passages that contain words or phrases that should be parallel (but are not) force the reader's brain into much more complicated but impromptu efforts at revision. Often these longer instances of nonparallelism are the ones that will bubble into consciousness as the reader stops and thinks, "He really lost me there." Here's an example.

> Chest-wall stethoscopes, particularly the weighted models now available, are suitable monitors for patients who are awake, during induction or with mask-administered anesthetics.

Confusion indeed! Are the patients awake during induction of anesthesia? For whom are these stethoscopes suitable monitors? The writer of this sentence has devised an ingeniously nonparallel way of presenting his facts. Actually, once we've wrestled this information into submission it becomes obvious that three groups of patients are referred to—awake patients, patients having anesthesia induced, and patients having anesthetic gases given via a mask. But it takes a little mental computation to be sure. The author should have written something like this:

> Chest-wall stethoscopes, particularly the weighted models now available, are suitable monitors for patients who are awake, are having anesthesia in-

duced, or are having anesthetics administered via a mask.

That sentence contains proper parallelism. The published version was potentially confusing, which is a serious fault itself. But nonparallelism can be actually misleading. Consider this advice for patients:

General measures, such as rest, temperate habits, avoidance of activity, and the use of alcoholic beverages, should not be forgotten.

The literal, grammatical (but not necessarily correct) meaning of this sentence is clarified by numbering the measures that are listed after the "such as" phrase:

General measures, such as (1) rest, (2) temperate habits, (3) avoidance of activity, and (4) the use of alcoholic beverages, should not be forgotten.

Plainly, although the author cautions patients to have temperate habits, he also advises them to use alcoholic beverages. Is this what he really means? Of course not. But haste and carelessness have led him to publish an ambiguous recommendation. Probably be meant "avoidance of" to encompass both "activity" and "the use of alcoholic beverages." But that isn't what he wrote. He should have written something like this:

General measures should not be forgotten—e.g., rest and adoption of temperate habits, together with avoidance of activity and of alcoholic beverages.

This revision logically pairs the things a patient should do and then pairs the things he shouldn't do. The message is clear and unequivocal.

Some English constructions require parallelism. These constructions are linked comparisons using correlative conjunctions such as "both . . . and," "either . . . or," and "not only . . . but also." I think that "either . . . or" is the most abused of these couplets. This next sentence exemplifies the nonparallelism that often arises:

The Mycoplasmas were identified either by their ability to split urea or typical colonial morphology as shown on buffered agar.

As written, the sentence grates on a reader's mind. He might logically expect the Mycoplasmas' ability to split urea to be followed by a description of their ability to split something else. There is a rule that should be applied: Express parallel ideas in the same grammatical form; whatever part of speech follows *either* should also follow *or*. If the author had followed this rule, the sentence would have been clearer. In this case, parallelism would have been furthered by adding a second preposition (*by*) and "their," as in this revision:

The Mycoplasmas were identified either by their ability to split urea or by their typical colonial morphology as shown on buffered agar.

The human mind is adept at listing and at comparing. When an author omits parallelism, the brain must work needlessly to provide what the author did not. Let's save brainpower for the necessary jobs.

Regards,

[Charles G. Roland, M.D.]

LACTIC ACIDOSIS Idiopathic lactic acidosis may arise from excessive production of lactic acid in any tissue or from an inability of the liver to metabolize lactate. A case is described in which sodium nitroprusside administered to a patient with congestive heart failure and idiopathic lactic acidosis had the unexpected effect of improving the acidemia (pH rising from 7.19 to 7.61). It was speculated that vasodilation caused redistribution of the cardiac output (possibly increasing hepatic blood flow) such that lactic acid metabolism was restored. *(Taradash MR, Jacobson LB: Vasodilation therapy of idiopathic lactic acidosis. NEJM 293:468-471, 1975)*

Case History Number 88: Gas Embolism During Encephalography

WILLIAM L. PAUL, MD
EDWIN S. MUNSON, MD

Patient #1.—A 14-year-old male was admitted to the hospital with a two-week history of intermittent headache, vertigo, anorexia, nausea and vomiting. Three years previously a suboccipital craniotomy had been performed for removal of a pineal teratoma and placement of a ventriculoperitoneal shunt. Physical examination on the present admission was unremarkable except that the ventriculoperitoneal shunt did not appear to be functioning properly. The neurosurgeons thought that the shunt was nonfunctional, that some degree of hydrocephalus was present, and the patient was scheduled for pneumoencephalography. Preoperatively, he received pentobarbital 100 mg, atropine 0.4 mg IM, and on arrival in the x-ray department he appeared sedated. A catheter was placed in a forearm vein for the administration of small doses of Innovar. After the patient was in the pneumoencephalographic chair, a ventriculostomy was performed. A pressure transducer was attached to the ventriculostomy catheter which showed the opening pressure to be 2 torr. Oxygen was used as the contrast gas medium. After several exchanges of cerebral spinal fluid for gas, a total of 50 ml oxygen was injected into the ventricular space. At this time the patient became restless and 50 percent nitrous oxide inhalation was administered by mask. Ventriculograms revealed that the ventricles were not well outlined and contained only a small amount of contrast medium. It was also noted that the CSF pressure remained at 2 torr. An explanation for these findings became apparent when it was noted on the ventriculogram (fig 1) that gas was present within the ventricular shunt tubing. It was concluded that the ventriculoperitoneal shunt was functional and that no hydrocephalus nor obstruction to ventricular fluid dynamics was present. The procedure was concluded and the patient made a satisfactory recovery. Three months later the patient died and at autopsy a hypothalamic tumor was found.

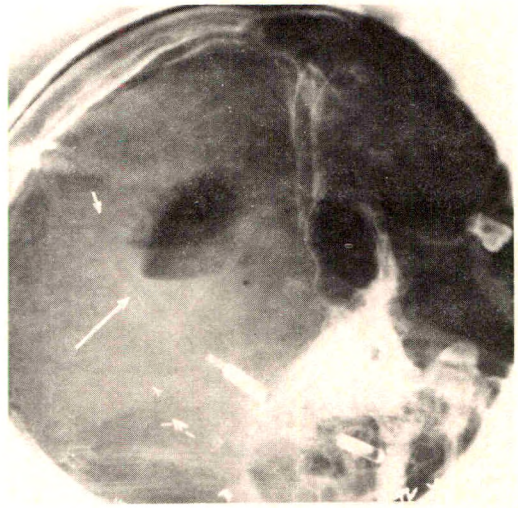

FIG 1. A ventriculogram with the patient in the brow-up position shows the contrast gas (oxygen) in the anterior horns of the lateral ventricles. Note the presence of gas within the shunt catheter (long arrow). The catheter tip is identified by the short arrow. The body of the shunt apparatus and surgical clips from a previous operation also are visible.

This manuscript was supported in part by a grant from the United States Public Health Service, Grant #GM00427-12.

This feature is conducted by Edwin S. Munson, M.D., Department of Anesthesiology, University of Florida College of Medicine, Gainesville, Florida 32610.

Patient #2.—A 6-year-old female was admitted to the hospital with a three-day history of intermittent headache and decreased appetite. At four months of age she was found to have severe communicating hydrocephalus and underwent placement of a ventriculoatrial shunt. The shunt functioned normally until the present admission when hydrocephalus secondary to a non-functional shunt mechanism was diagnosed. Hematologic and blood chemistries were within normal limits.

The patient was scheduled for ventriculography. Preoperatively she received pentobarbital 65 mg, meperidine 20 mg, and atropine 0.3 mg IM and she was well sedated on arrival for the procedure. After she was placed in the pneumoencephalography tilt chair, catheters were positioned in peripheral and central veins. Anesthesia was induced with 75 mg thiopental IV and intubation was facilitated by 40 mg succinylcholine. Anesthesia was maintained with halothane, one percent in combination with nitrous oxide in 50 percent concentration. An esophageal stethoscope was used to monitor heart sounds.

Because of the experience with the ventricular shunt in the previous patient, it was elected to use nitrous oxide as the contrast gas medium. Approximately 15 ml of nitrous oxide were injected in divided doses into the shunt reservoir. To distribute the gas within the ventricular system, the patient was rotated 360° in the saggital plane, as if performing a forward somersault. When the patient returned to the original supine position, a harsh high-pitched systolic murmur was heard. No change in pulse rate or arterial blood pressure occurred. Nitrous oxide was immediately discontinued from the inspired gas and the lungs were ventilated with 100% oxygen. The cardiac murmur gradually disappeared over the next five minutes. Repeated attempts to aspirate blood through the central venous catheter were unsuccessful. After an additional five-minute period, when normal heart sounds had returned, nitrous oxide inhalation was reinstituted. Almost immediately the cardiac murmur returned. Nitrous oxide was discontinued and the procedure terminated. The ventriculogram showed the tip of the ventricular catheter to be within the anterior horn of the right lateral ventricle.

The patient was placed in the left lateral decubitus position and oxygen was administered through the endotracheal tube. Thirty minutes later, analysis of arterial blood gases showed oxygenation and ventilation to be normal. Chest x-rays at this time were also normal. An hour later the endotracheal tube was removed and the patient recovered without incident.

DISCUSSION

With the development of ventriculoatrial and ventriculoperitoneal shunts to control CSF pressure and hydrocephalus, anesthesiologists often are involved with the management of these patients during pneumoencephalography. Frequently, as presented in Case History #1, the evaluation involved determining shunt patency. A crude clinical assessment of shunt function is usually made by depressing the shunt reservoir. If the reservoir fills in less than one minute the volume of ventricular CSF may be normal or elevated. If the ventricles are collapsed as a result of decreased CSF pressure, or from shunt malfunction, the reservoir will not fill.

This case shows another method for determining shunt patency which has not previously been reported, namely, the failure of CSF pressure to rise following inhalation of nitrous oxide when air or oxygen is used as contrast gas media. The hazard of rapid and severe increases in CSF pressure during air encephalography during nitrous oxide anesthesia has been described by Saidman and Eger.[1] This mechanism results from the greater solubility of nitrous oxide in blood compared with nitrogen. The differential solubility between nitrous oxide and oxygen (about 1:6) also should result in an increase in CSF pressure, but to a lesser extent than with air. This patient (#1) did not exhibit any increase in CSF pressure, probably the result of the functioning shunt. Had a ventriculoatrial shunt been present venous embolism undoubtedly would have occurred as observed in patient #2.

Venous air embolism has long been recognized as a complication of pneumoencephalography.[2] The events described with patient #2 and the recent report of Youngberg et al[3] illustrate this potential hazard in patients with ventriculoatrial shunts. In this regard, the selection of the contrast medium (air, oxygen, or nitrous oxide) is important. During inhalation of nitrous oxide, no increase in CSF pressure results when the contrast gas also is nitrous oxide.[4] This technic appears to offer maximal safety in preventing a rise in CSF pressure.

However, should venous embolization of nitrous oxide occur, the embolized bubbles would tend to be held in the gas phase due to the high partial pressure of the anesthetic in venous blood. Thus, embolized nitrous oxide would be rendered "insoluble" in venous blood until pulmonary excretions of nitrous oxide occurred. When discontinued from inspired gases, nitrous oxide is rapidly eliminated from the lung, blood and cerebral ventricles. Furthermore, relatively rapid absorption of intraventricular nitrous oxide would prevent the occurence of delayed gas embolism.[5] When oxygen is used as the contrast gas medium, some rise in CSF pressure may occur, but the low partial pressure of oxygen in venous blood would tend to maintain a relatively greater solubility thus promoting gas absorption which would not be affected by the presence of nitrous oxide. However, since oxygen may linger in the cerebral ventricles for as long as 24 hours following encephalography[6] the patient would have to be carefully observed in the postanesthetic period.

Youngberg et al[3] have suggested that venous air embolism during encephalography can be avoided or minimized in patients with ventriculoatrial catheters by: 1) attempting to keep the air fluid level above the tip of the shunt catheter; 2) avoiding air as a contrast medium; 3) using a central venous catheter for gas aspiration; 4) continuously monitoring ECG; 5) using the Doppler flow probe monitor over the right heart; and whenever possible, 6) ligating or clamping the shunt catheter prior to encephalography.

Additional monitors which would facilitate early detection of venous air embolism also include end-tidal CO_2 monitoring during constant volume ventilation and the use of a Swan-Ganz catheter for continuous measurement of right ventricular or pulmonary artery pressures.[7] Should venous air embolism occur, the treatment is symptomatic and directed toward preventing further air entry and restoring normal cardiopulmonary function. Placement of the patient in the left lateral decubitus position is advantageous because the apex of the heart is placed above the level of the pulmonic

Comment

ROBERT K. STOELTING, M.D.

Gas encephalography requiring inhalation anesthesia may produce changes that require an understanding of differential gas solubility. For example, increased intracranial pressure during N_2O inhalation and air or oxygen injection into the cerebral ventricles occurs because of the greater solubility of nitrous oxide as compared with nitrogen. The present report describes a possible diagnostic use of N_2O inhalation to determine patency of a ventriculoperitoneal shunt and emphasizes the hazards of venous air embolism and the rationale for the contrast and anesthetic gases chosen in the presence of a functional ventriculoatrial shunt.

An additional consideration when using N_2O as the contrast gas is its rapid disappearance from the ventricles when N_2O inhalation is discontinued. This has resulted in rapid reduction of CSF pressure and subsequent cardiovascular collapse.[1]

A method providing similar information as gas encephalography but not requiring a contrast gas would be useful. Computer-assisted transverse axial tomography (EMI scanner) permits such an examination. Furthermore, sedation is necessary only for the uncooperative patient. It is unlikely that this radiologic technic will completely eliminate the need for gas encephalography but the frequency will surely be reduced. Indeed, in a recent report, the number of gas encephalograms decreased 60 percent following the introduction of the EMI scanner.[2]

valve, thus promoting relief of right ventricular outflow obstruction and clearance of intracardiac gas.[8] The pneumoencephalography tilt chair facilitates placing the patient in this position. Elimination of nitrous oxide from the lung will reverse the bubble amplification effect on intrapulmonic bubbles[9] and an increased F_{IO_2} will tend to overcome the hypoxemia caused by intrapulmonary shunting. The use of vasopressors and closed-chest cardiac massage also have been advocated for the treatment of profound arterial hypotension and cardiac arrest.[10]

Comment

JOHN A. YOUNGBERG, M.D.,
Major, MC
Department of Anesthesia
Brooke Army Medical Center
Fort Sam Houston, Texas 78234

The two cases present possible complications of central nervous system diagnostic procedures performed when patent ventriculoperitoneal or ventriculoatrial shunts are present. They demonstrate why patients with such shunts should be carefully monitored and why an anesthesiologist should be in attendance.

Case #1 demonstrates the embolization of the contrast gas through the shunt to the peritoneal cavity. This apparently resulted in no injury to the patient and showed the patency of the shunt.

Case #2 is more interesting. We previously have described embolization through a patent ventriculoatrial shunt and its possible sequelae.[1] Approximately 90% of patients with gas emboli develop murmurs; 65% develop arrhythmias, and 68% have hypotension.[2] The authors report the presence of a "harsh, high-pitched systolic murmur" in this patient, but do not report the occurrence of hypotension or an arrhythmia. The central venous catheter apparently was not functional precluding confirmation of diagnosis by aspiration of gas. Without measuring aspiration of gas from the heart, the diagnosis of gas embolization is tenuous unless there is a sudden onset of a murmur accompanied by a significant alteration in cardiac rhythm or arterial blood pressure.[2]

An attempt was made to duplicate events in this case in a dog model.† A 20.4 kg mongrel dog was anesthetized with 1% halothane and 50% nitrous oxide in oxygen. Respirations were controlled. A central venous catheter was placed in the right external jugular vein, attached to a strain gauge, and advanced until a right atrial wave form was obtained. A Doppler chest probe was positioned over the heart. A 7 ml (0.3 ml/kg) bolus of nitrous oxide was administered through the central venous catheter. A harsh, systolic murmur was heard almost instantly and the animal was ventilated with oxygen. During the time the murmur was audible, there was a marked drop in pulse pressure but no change in pulse rate or any audible change in cardiac rhythm. After 2.5 minutes, the murmur was no longer audible. Ventilation with oxygen was continued for an additional five minutes when 1% halothane and 50% nitrous oxide in oxygen was reinstituted. There was no recurrence of any cardiac murmurs.

This experiment raises questions as to

*The opinions or assertions contained herein are the private views of the author and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.

†Appreciation is expressed to Gary Welch, M.D., Brian Ribak, M.D., and Mr. Walker in performing the animal experiment.

the etiology of the recurrence of the murmur described in Case #2. Nitrous oxide embolization could have been continued through the shunt to the heart, or a quantity of air may have inadvertently been injected into the ventricular system together with the nitrous oxide, thus producing nitrous oxide-air embolization. In this latter case, when nitrous oxide inhalation was discontinued, the size of the bubble would decrease secondary to absorption of nitrous oxide into the blood and loss of the murmur, but would again increase in size when nitrous oxide inhalation was instituted. However, in this patient, the time sequence makes this possibility unlikely.

The patency of a ventriculoatrial shunt may be evaluated by employing a contrast material such as meglumine iothalamate 60%, prior to performing diagnostic procedures. However, potential hazards of seizure activity or arachnoiditis exist with such agents.[3,4] In the presence of a patent shunt, it may be more advantageous to utilize meglumine iothalamate 60%, or carbon dioxide, to perform such studies.[1]

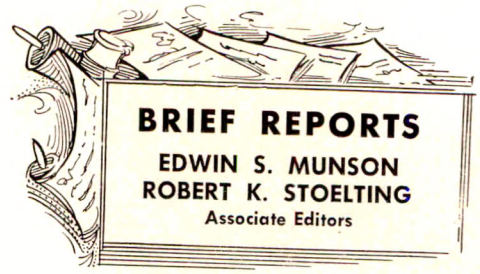
INTRAVENOUS FLUIDS An intravenous solution that could reduce protein wasting and be administered through peripheral veins would be useful postoperatively until an adequate oral intake could be established. The metabolic effects of a 3 per cent amino acid solution vs a 5 per cent dextrose solution were compared during the first 6 postoperative days after head and neck or abdominal operations. Nitrogen losses for patients receiving the amino acid solutions were significantly less than for patients receiving 5 per cent dextrose. Phlebitis occurred with equal frequency in both groups. The speculated mechanism for nitrogen sparing was decreased serum glucose and insulin levels allowing greater fat mobilization and utilization with subsequent sparing of lean body mass. *(Hoover HC, Grant JP, Gorschboth C et al: Nitrogen-sparing intravenous fluids in postoperative patients NEJM 293:172-175, 1975)*



Fire Hazard During CO_2 Laser Microsurgery on the Larynx and Trachea

JOHN C. SNOW, MD*
MARTIN L. NORTON, MD†
TEJINDER S. SALUJA, MD‡
ADORACION F. ESTANISLAO, MD§
Boston, Massachusetts‖

In a previous report,[1] we described the use of the CO_2 laser for microsurgery on the larynx and trachea in 392 procedures under general endotracheal anesthesia. No morbidity or mortality was found related to this technic. We have now performed a total of 700 such procedures on 250 patients over a 42-month period (1972-1975). No side effects related to the procedure had been seen, nor had there been any injuries to patients or operating room personnel. However, within the last 6 months, 4 patients sustained burns of the tracheal mucosa from the impact of the laser beam on the endotracheal tube. In all 4 cases, the fire was extinguished promptly and the burns healed uneventfully. Two of the cases will be described in detail.

REPORT OF CASES

Case 1.—A 12-month-old girl was admitted to the hospital with a tracheotomy since the age of 3 months and recurrent laryngeal papillomas which produced complete obstruction of the larynx. The following day, induction and maintenance of anesthesia were accomplished with nonflammable anesthetics, and an uncuffed red-rubber Rusch endotracheal tube was inserted through the tracheotomy. The tube was not wrapped with aluminum tape. The larynx was exposed with a pediatric laryngoscope and placed on the suspension apparatus. A Zeiss operating microscope with laser attachment was brought into position.

When the laser beam was continuously

discharged, the papillomas obstructing the larynx were vaporized, so that the laser beam impacted on the tube within the trachea at the tracheotomy level. A fire started, which was brought under control immediately, by removal of the burning tube. Examination of the endotracheal tube revealed a superficial burned area, 1 x 0.5 cm in size, 4 cm from the distal end. Bronchoscopy revealed a small superficial burn of the tracheal mucosa, which later healed.

Case 2.—A 12-year-old boy was anesthetized with nonflammable anesthetics for CO_2 laser microsurgery of recurrent laryngeal papillomas. An uncuffed red-rubber Rusch oral endotracheal tube was used and was protected with aluminum foil except for the distal 1.5 cm of the tube. During the operation, the laser beam repeatedly hit the unprotected distal end of the tube. A fire started, which was brought under control immediately by removal of the burning tube. Examination of the tube showed a superficial burned area, 1.2 x 0.5 cm in size, including the aperture opposite the beveled end of the endotracheal tube. Bronchoscopy revealed a small superficial burn of the tracheal mucosa, 1 cm below the vocal cords, which healed uneventfully.

DISCUSSION AND SAFETY PRECAUTION RECOMMENDATIONS

The wavelength of the CO_2 laser beam is in the infrared range (10.6 microns), so the destructive capacity of the beam is limited to a thermal effect. The heat produced may ignite unprotected anesthesia equipment or flammable anesthetic agents. Plastic and rubber equipment, such as endotracheal tubes, oropharyngeal airways, nasogastric tubes, and esophageal stethoscopes, easily can be set on fire by a misdirected laser beam.

During CO_2 laser microsurgery on the larynx and trachea, we have observed that if the laser beam repeatedly hits the red-rubber Rusch endotracheal tube (4 or 5 times) in the same area, there is the risk of fire. The laser beam must be carefully focused to avoid impact with the tube.

If a patient has a tracheotomy, anesthesia can be administered either through a metal tracheotomy tube or a Rusch red-rubber endotracheal tube. However, if the red-rubber endotracheal tube is situated within the operative field, it must be protected with a reflective surface in order to avoid laser beam damage and fire. A thin metal coating, such as self-adhesive aluminum tape, placed around the distal portion of the tube, not including the cuff, will protect the tube from accidental laser impact. The cuff cannot be protected without limiting its function.

Fewer safety precautions are necessary with CO_2 laser than with ruby, argon or other lasers. The operating room personnel need only to wear ordinary eyeglasses to protect their corneas from injury should the laser beam accidentally be reflected from a metal surface. For the same reason, the patient's eyes also must be taped shut. If an area of tissue close to the target area needs to be protected, it can be shielded adequately by moist gauze, since water dissipates the energy effectively. Pregnant personnel are not at risk. The laser beam is not like an x-ray, in that its effects are limited to accessible areas.

All nonflammable inhalation anesthetic agents can be administered to patients undergoing laser surgical procedures.[2] The potential electrical and explosive hazards associated with the use of the laser are no greater than those with the use of high-frequency electrosurgery.[3]

A New Introducer for Percutaneous Cardiovascular Catheters

JOHN M. GOODING, DO*
GUENTER CORSSEN, MD†
Birmingham, Alabama‡

SINCE its introduction, the Swan-Ganz catheter has been effective for evaluation of myocardial performance. Because of the seemingly complicated technic of inserting the catheter, as originally described by the authors,[1] many clinicians still prefer the placement of central venous pressure lines. The recent development of an introducer§ has made central venous sites more accessible for pulmonary artery catheterization. The introducer consists of a 17-gauge needle covered by an inner and outer plastic sheath (figure). The special design of the introducer makes possible the percutaneous puncture of the internal jugular or subclavian vein, as described elsewhere.[2-4]

The basic technic of catheterization involves the following steps:

1. Surgical preparation with antimicrobial solution and appropriate draping.

2. Local infiltration of the site of vein puncture with a suitable local anesthetic.

3. Small stab wound through the skin and subcutaneous tissue with a #11 scalpel blade.

4. Advancement of the introducer, to which a 10 ml syringe is attached, into a central vein, and aspiration of venous blood.

§Percutaneous Cardiovascular Catheter Introducer, Edwards Laboratories, Santa Ana, California.

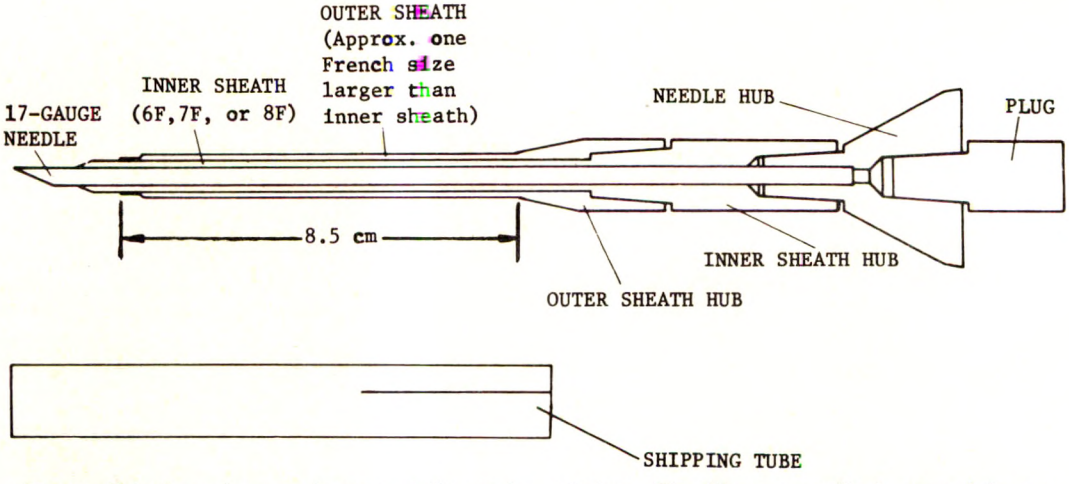

FIGURE. Introducer for percutaneous cardiovascular catheters. The 17-gauge needle is covered by an inner and outer plastic sheath.

5. Upon successful venous aspiration, the introducer is advanced (approximately 0.5 cm) to ensure intravascular placement of the needle bevel as well as the distal tips of the inner and outer plastic sheaths.

6. The needle is withdrawn and the inner and outer sheaths are advanced simultaneously.

7. The hub plug is attached to the hub of the inner sheath to prevent excessive venous backflow in high venous pressure states and air embolization in low venous pressure states.

8. When catheterization is about to begin, the inner sheath is withdrawn, holding the outer sheath in place, and the catheter is rapidly introduced through the outer sheath.

9. Once the catheter is advanced to 10 cm within the vein, the outer sheath can be removed from its intravenous site and drawn snug proximally on the catheter, where it is held in place.

It is preferable to inflate the balloon when the catheter is approximately 10 to 12 cm within the vein. The catheter is then connected to a pressure transducer and the pressure wave is recorded either on an oscilloscope or write-out recorder. While advancing the catheter, the location of its tip is determined by observing the changes in the contour of the pressure wave.

DISCUSSION

Originally, the pulmonary artery catheter was inserted via an antecubital vein cutdown.[1] It has been our experience that this approach is frequently unsuccessful, due to site inaccessibility or failure in traversing the shoulder veins. The antecubital cutdown approach is also time consuming. If the catheter is not passed to the pulmonary artery within a reasonable time after initial insertion from the antecubital fossa, the catheter is warmed by body temperature and becomes pliable, leading to possible looping or knotting and to difficulty in advancing.

With access through a central vein, pulmonary artery catheterization can be rapid, simple, and does not require a cutdown. The technic has a higher incidence of success, can be used when peripheral sites are not accessible, and follows a more direct route to the right heart than the peripheral approach. There seems also to be a lesser incidence of thrombophlebitis.

To date, we have completed 82 catheterizations with the percutaneous cardiovascular introducer. The only reportable complication has been one incidence of pneumothorax in a patient with clavicular anatomic abnormality due to an old fracture. Minor oozing may occur around the puncture site; however, this may be effectively controlled with adequate local compression. We have had no other complications related to use of the introducer.

Plastic Covered Solid Copper Wire Stylet

MORRIS J. NICHOLSON, MD
Boston, Massachusetts*

AN EFFECTIVE and inexpensive flexible stylet can be made from commercially available #12 TW (thermoplastic weatherproof) copper wire (figure, A). The proximal looped end can be held tight by using a 9-mm heat-shrinkable plastic tube (figure, B). Sterilization is by soaking in alcohol, autoclaving, or exposure to ethylene oxide. The distal end of the plastic end of the plastic tubing covering the copper wire can be heat sealed.

*Will present paper.

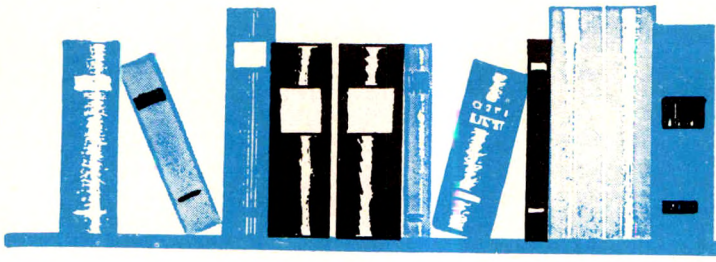
NOTE

Program content, as well as days and times of presentation are subject to change, and any changes will be included in the final program distributed at the meeting. The final program will also contain abstracts of the scientific papers, as well as names and professional affiliations of all individuals involved in the preparation, presentation or discussion of the papers.



the book shelf

Public Health Aspects of Critical Care Medicine and Anesthesiology — Safar, Peter, M.D., Editor. Philadelphia, FA Davis Company, Clinical Anesthesia, 1974, vol 10, no 3, 396 pp, price $20.00.

The objective of this contribution to the *Clinical Anesthesia* series is to give the reader, in particular physicians and other health-care professionals, a broad view and assessment of the current systems of medical-care delivery and the associated unsolved problems and their possible solutions. "Public health" in this context refers to community medical-care systems and the planning, implementation, and evaluation of health-care delivery programs.

For the most part, the topics relate directly to the role of the anesthesiologist in health-care delivery; areas of concern include resuscitation and life-support, emergency medical care, and intensive care.

Inclusion of "critical-care medicine" certainly reflects the editor's well-known interests and concern for this area of medical practice—an area to which Dr. Safar has made many and major contributions. In fact, in those chapters authored by Safar, there emerges a rather clear picture and perception of his own philosophies and strongly-worded opinions. For example, on page 15: "In the 1950s disasters were considered mainly from the point of view of nuclear war. Millions of dollars were spent to satisfy the Cold War paranoia of certain governmental agencies, although we lacked the most basic emergency care for everyday needs." Safar knows well from personal experience, some of which he shares in this book, the frustrations of attempting to upgrade emergency services in the face of apathy and frank and bitter opposition.

Here are some of the many areas surveyed: Centralization of hospital care for the critically ill; hospital and emergency facility categorization; current status of respiratory-care services in the United States; surgical and anesthesia workloads, anesthesia mortality; anesthesia manpower and allied health personnel in anesthesia; outpatient anesthesia; and anesthesia costs. Of course, cardiopulmonary resuscitation and emergency and critical-care systems are discussed at length.

It should be apparent that there is something for nearly everyone in this volume. In spite of multiple authorship, there is very little duplication, perhaps because each chapter "stands on its own" and covers distinct yet related material. It is an informative text and will be useful as a resource for many areas of anesthesiology and critical-care medicine.

Life-Threatening Emergencies in the Dental Practice — Schijatschky, Milan M., Berlin, Chicago, Quintessence Books, 1975, 163 pp.

To quote from the introductory paragraph of this interesting and informative book: "There is no such thing as a life-threatening emergency specific to the dental office," is good reason for the dental practitioner to become familiar with any situations that may require emergency measures in his office.

The author has presented this subject in considerable depth and has included much valuable information and directives for the benefit of the dental practitioner.

This should be a very useful source of information for students and practitioners in the dental profession.

A Guide for Authors

Anesthesia and Analgesia . . . Current Researches invites original manuscripts on subjects pertinent to the specialty of anesthesiology. Original articles accepted for publication, or papers presented at the Society's annual scientific meetings which subsequently may be published in the Journal, become the property of the International Anesthesia Research Society. Reproduction in whole or in part is not permitted except by written consent of the publisher and the author.

Submit manuscripts in triplicate to—
T. H. Seldon, M.D., Editor
Kahler East, Suite C
Rochester, Minnesota 55901, U.S.A.

All papers are reviewed by the Editorial Board and other selected referees. If accepted for publication, editorial revisions may be made to aid clarity and understanding without altering the meaning. Edited copy is submitted to authors for approval before it is sent to the printer. Page proof will be submitted to authors for final approval. Reprint order forms will accompany page proof.

Titles should be concise but informative, with thought given to the use of key words for indexing. Ninety characters, including punctuation and spaces, should be sufficient.

Coauthors' names should be followed by the major degree, professional affiliation, and address.

Abstract: On the first page of manuscript, an abstract of from 50 to 250 words, according to length of article, but not exceeding one double-spaced typed page, should describe purpose, methods, results, and conclusions, as succinctly as possible. This replaces both former Capsule Review and Summary, but is the same in content and format.

Type manuscript (in triplicate) on 8½ x 11-inch white paper, with 1½ inch margins at top, bottom, and both sides. Double space ALL typing, including references, legends and footnotes.

References: About 20 references are acceptable. In extensive reviews of the literature, readers will be advised that longer reference citations can be obtained from author. Citations should include (1) last name of author followed by initials without internal punctuation; (2) commas separate names and initials of authors; (3) four or more authors are designated as "et al;" (4) journal name is abbreviated according to Index Medicus style; (5) references from books show (a) city of publication, name of publisher, date of publication, after book title; (6) journal references give volume, first and last page numbers, year. (See previous issues of *Anesth & Analg* for style.)

Tables should be self-explanatory and should supplement, not duplicate, the text.

Photographs should have sharp contrast, be on *glossy* paper unmounted, and 4 by 5 inches or larger. *Polaroid prints damage easily in handling and thus may reproduce indistinctly. Glossy prints are preferred.* Submit photographs of roentgenograms with contrasts as in original and sharply defined; "TOP" must be identified. All illustrative materials, charts, etc., must be submitted in triplicate, clearly numbered according to text and legend.

Lettering on charts and graphs must be large enough to be legible when reduced in size. Curves, scatter dots, etc., should contrast with reference lines.

Drawings must be in black (India) ink on white background and should be of professional quality.

Legends for illustrations should be concise and typed on one page. Legends for photomicrographs should show stain and magnification data.

Drug names used in the text should be generic unless trade names are essential to the discussion.

Multiple Publication: To avoid violating existing copyrights, a statement should accompany each submitted article indicating that the material in question:

1. Has not been simultaneously submitted to another journal.
2. Has not been previously published elsewhere.

a. Abstracts of 400 words or less do not constitute prior publication.

b. A report issued by requirement of a governmental agency or comparable granting institution does not constitute prior publication.

c. Extracting by news media does not constitute prior publication unless all vital tables and pertinent conclusions are involved or unless such publication was actively solicited by the authors.

Legal considerations require letters of permission from authors and publishers for use of illustrations or quotations originally appearing elsewhere, and also written permission for use of photographs of identifiable patients. Identifying information, such as names, initials, hospital numbers, and dates, must be avoided.

When experimentation involving human subjects is reported, an appropriate statement regarding informed consent should be made.

Case reports should include only significant data. Laboratory findings should be restricted to those pertinent to the discussion.

Symbols used for respiratory physiology should follow Fed. Proc. 9:602, 1950.

Explanation of abbreviations and symbols used within the text should be added as a footnote.

Example: torr: Unit of pressure of 1 mm. of mercury at 0° C. and standard gravity.

CHECK LIST

A "quick recovery" anesthetic for short surgical procedures

Ethrane® (enflurane) fulfills your anesthetic requirements for short surgical procedures.

Fast Induction, Rapid Recovery. The low blood/gas partition coefficient of ETHRANE (1.91 at 37°C) assures rapid patient induction with minimal excitation. Its mild, pleasant odor is highly acceptable and ETHRANE does not stimulate increased salivation or affect bronchomotor tone.[1] Pharyngeal and laryngeal reflexes can be quickly and easily obtunded. Following anesthesia, because of its low blood solubility, ETHRANE is promptly eliminated at the lungs, permitting rapid emergence and recovery.[2]

Stable Cardiac Rhythm. Cardiac rhythm usually remains normal during ETHRANE anesthesia and is not altered even with elevations in arterial carbon dioxide.[3] Although nodal or atrial arrhythmias occasionally appear, ventricular extrasystoles are rare. Heart rate is sustained at preanesthetic levels. Bradycardia or tachycardia do not normally occur. Blood pressure tends to be reduced with induction, but this effect is reversed with surgical stimulation.[4]

Excellent Muscle Relaxation. At clinical concentrations, ETHRANE usually provides muscle relaxation sufficient for lower abdominal procedures. In addition, relaxation is often adequate for procedures of the upper abdomen. If greater relaxation is required, its potentiation of nondepolarizing relaxants reduces the dosage of such adjunctive neuromuscular blocking agents.[4]

Few Anesthetic Aftereffects. Following cessation of anesthesia with ETHRANE, recovery is rapid, uneventful, and complete. Postoperative return of adequate pulmonary ventilation is rapid.[1] Nausea, vomiting, and delirium are rare. Usually there is an early return of lucidity, desire for fluids, and generally a feeling of well-being.[1,5]

WARNING: Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. For additional warnings, contraindications, and precautions, see following page.

Films Available for Medical Education. As a service to the anesthesia profession, Ohio Medical Products has available, without charge, motion pictures for use in continuing medical education. Topics include such areas as "Management of Ambulatory Surgical Procedures" and "The Use of ETHRANE." To arrange for a personal or group showing, contact your OHIO Anesthetic Representative, or write to our Communications Department in Madison, Wisconsin.

Ethrane® (enflurane) Versatile in concept... Versatile in performance.

CAUTION: Federal Law Prohibits Dispensing without Prescription

Description: ETHRANE (enflurane) is a nonflammable anesthetic agent. It is 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether, and its structural formula is:

Some physical constants of the compound are:

Molecular weight	184.5
Boiling point 760 mm Hg.	56.5°C
Refractive index n_D^{20}	1.3026-1.3030
Specific gravity 25°/25°C	1.517
Vapor pressure in mm Hg.**	20°C 174.5 25°C 217.7 36°C 345.2

**Equation for calculation of enflurane vapor pressures:

$$\log_{10} P = A + \frac{B}{T}$$

A = 7.967
B = −1678.4
T = °C + 273.16 (Kelvin)

Partition coefficients @ 37°C	
Water-gas	0.82
Blood-gas	1.91
Oil-gas	98.5
Partition coefficients @ 25°C— rubber and plastic	
Conductive rubber	74.0
Butyl rubber	90.0
Polyvinylchloride	120.0
Polyethylene	∼2.0
Polyurethane	∼1.5
Polyolefin	∼1.2
Butyl acetate	∼3.0
Solubility of enflurane in H_2O at 22°C	0.275%
Solubility of H_2O in enflurane	0.13%
Purity by gas chromatography	>99.9%
Flammability in air	None
Flammability in oxygen (Entire concentration range to saturation at 71 and 113°F and 743 mm Hg. pressure.)	None
M.A.C. (Minimum alveolar concentration)	
Man with pure oxygen	1.68
Man with 70% nitrous oxide	0.56 (est.)

ETHRANE is a clear, colorless, stable liquid without added chemical stabilizers. ETHRANE has a mild, sweet odor. Storage of samples in indirect sunlight in clear, colorless glass for a five year period, as well as direct exposure for 30 hours to a 2 amp, 115 V., 60 cycle long wave U.V. light, produced no changes in composition detectable by gas chromatography. ETHRANE in one normal sodium methoxide-methanol solution, a strong base, for over six months consumed none of the alkali, indicative of strong base stability. ETHRANE does not decompose in contact with soda lime. ETHRANE does not attack aluminum, tin, brass, iron or copper.

Actions: ETHRANE (enflurane) is an inhalation anesthetic. Induction and recovery from anesthesia with ETHRANE are rapid. ETHRANE does not appear to stimulate excess salivation or tracheobronchial secretions, or affect bronchomotor tone. Pharyngeal and laryngeal reflexes are readily obtunded. The level of anesthesia changes rapidly with ETHRANE. ETHRANE reduces ventilation as depth of anesthesia increases. ETHRANE provokes a sigh response reminiscent of that seen with diethyl ether.

There is a decrease in blood pressure with induction of anesthesia, followed by a return to near normal with surgical stimulation. Progressive increases in depth of anesthesia produce corresponding increases in hypotension. Heart rate remains relatively constant without significant bradycardia. Electrocardiographic monitoring or recordings indicate that cardiac rhythm remains stable. Elevation of the carbon dioxide level in arterial blood does not alter cardiac rhythm. ETHRANE sensitizes the myocardial conduction system to epinephrine in dog and can produce serious arrhythmias. Comparable information in man is not available.

Muscle relaxation is adequate for intra-abdominal operation at normal levels of anesthesia. Should greater relaxation be necessary, minimal doses of muscle relaxants may be used. All commonly used muscle relaxants are compatible with ETHRANE. **The nondepolarizing muscle relaxants are markedly potentiated.** Neostigmine does not reverse the direct effect of ETHRANE.

Biotransformation of ETHRANE (enflurane) in man results in low levels of serum fluoride ions averaging 15 mM/L. These levels are well below the 50 mM/L seen to produce renal damage in normal subjects; however, it is possible that these levels could result in damage in patients with severely impaired renal function or those undergoing renal transplantation.

Indications: ETHRANE (enflurane) may be used for induction and maintenance of general anesthesia. Adequate data have not been developed to establish its application in obstetrical anesthesia.

Contraindications: Seizure disorders (see WARNINGS).

Known sensitivity to ETHRANE (enflurane) or other halogenated anesthetics.

Warnings: Increasing depth of anesthesia with ETHRANE (enflurane) produces a change in the electroencephalogram characterized by high voltage, fast frequency, progressing through spike-dome complexes alternating with periods of electrical silence to frank seizure activity. The latter may or may not be associated with motor movement. Motor activity, when encountered, generally consists of twitching or "jerks" of various muscle groups; it is self-limiting and can be terminated by lowering the anesthetic concentration. This electroencephalographic pattern associated with deep anesthesia is exacerbated by hyperventilation producing low arterial carbon dioxide tension. The pattern serves as a warning that depth of anesthesia is excessive. Cerebral blood flow and metabolism studies in normal volunteers during seizure patterns show no evidence of cerebral hypoxia, and recovery appears to be uncomplicated.

Since levels of anesthesia may be altered easily and rapidly, only calibrated vaporizers which measure output with reasonable accuracy should be used. Hypotension and respiratory exchange can serve as a guide to anesthesia depth. With deep levels of anesthesia, more marked hypotension and respiratory depression are encountered.

The action of nondepolarizing relaxants is augmented by ETHRANE. Less than the usual amounts of these drugs should be used. The time for recovery from the myoneural effect of these relaxants is greater in the presence of ETHRANE than for other commonly used anesthetics.

The safety of the use of epinephrine topically and subcutaneously has not been established in man.

Usage in Pregnancy: Safety in pregnancy has not been established. Reproduction studies have been performed in rats and rabbits, and there is no evidence of harm to the animal fetus. The relevance of these studies to the human is not known. Since there is no adequate experience in pregnant women who have received the drug, safety in pregnancy has not been established.

Precautions: Bromsulfalein (BSP) retention is mildly elevated postoperatively in some cases. There is some elevation of glucose and white blood count intraoperatively. Glucose elevation should be considered in diabetic patients. ETHRANE (enflurane) should be used with caution in patients who by virtue of medical or drug history could be considered more susceptible to cortical stimulation produced by this drug. As with other general anesthetics and some muscle relaxants, hyperpyrexia has been observed with the use of ETHRANE.

Adverse reactions: 1. Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. 2. Hypotension and respiratory depression have been reported. 3. Arrhythmias, shivering, nausea, and vomiting have been reported. 4. Elevation of the white blood count has been observed. It has not been determined whether this is related to ETHRANE or to surgical stress.

Dosage and administration: The concentration of ETHRANE (enflurane) being delivered during anesthesia from a vaporizer should be known. This may be accomplished by using:

a) vaporizers calibrated specifically for ETHRANE;
b) vaporizers from which delivered flows can easily and readily be calculated.

Maintenance concentration should not exceed 3%. Premedication should be selected according to the need of the individual patient, taking into account that secretions are weakly stimulated by ETHRANE and the heart rate remains constant. The use of anticholinergic drugs is a matter of choice.

Induction: Induction may be achieved using ETHRANE alone with oxygen or in combination with oxygen-nitrous oxide mixtures. Under these conditions some excitement may be encountered. If excitement is to be avoided, a hypnotic dose of a short-acting barbiturate should be used to induce unconsciousness, followed by the ETHRANE mixture. In general, inspired concentrations of 3.5-4.5% ETHRANE produce surgical anesthesia in 7-10 minutes.

Maintenance: Surgical levels of anesthesia may be attained with 1.5-3.0% concentration. If added relaxation is required, supplemental doses of muscle relaxants may be used. Ventilation to maintain the tension of carbon dioxide in arterial blood in the 35-45 mm range is preferred to hyper- or hypoventilation in order to minimize possible CNS excitation.

The level of blood pressure during maintenance is an inverse function of ETHRANE concentration in the absence of other complicating problems. Excessive decreases (unless related to hypovolemia) may be due to depth of anesthesia and in such instances should be corrected by lightening the level of anesthesia.

Overdosage: In the event of overdosage, or what may appear to be overdosage, the following action should be taken:

Stop drug administration; establish that the airway is clear and initiate assisted or controlled ventilation with pure oxygen as circumstances dictate.

Administration equipment: ETHRANE (enflurane) may be administered from a flow-through type vaporizer manufactured and specifically calibrated for ETHRANE. Vaporizers which deliver saturated vapor at reasonable flows but are not specifically calibrated for ETHRANE may be used.

ETHRANE contains no stabilizer. Nothing is present in the agent to alter calibration or affect the operation characteristics of the vaporizer.

Packaging: ETHRANE (enflurane) is packaged in 125 and 250 ml. amber bottles. No additives or stabilizers are present.

Take the **Excessive Anxiety** out of **Anesthesia**

Vistaril I.M. (hydroxyzine HCl) helps allay the anxiety that may complicate premedication, induction and recovery room emergence.

It has no significant depressant effects on respiratory or circulatory function and often reduces postoperative emesis.

Vital signs are seldom impaired. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.

And, because it may enhance the effect of injectable analgesics, requirements of narcotic and nonnarcotic analgesics, such as meperidine, morphine sulfate and pentazocine, may be reduced.

Vistaril I.M. is physically compatible with most commonly used analgesics, and can be mixed with them in the same syringe.

Alone, or as an adjunct for use with injectable analgesics, the maximum recommended dosage of Vistaril I.M. is 100 mg. While the analgesic dosage needed will usually be reduced, the actual dosage of Vistaril I.M. should be titrated against the individual patient's clinical response.

Vistaril® I.M.
(hydroxyzine HCl)
100 mg./2 ml., 50 mg./ml. and 25 mg./ml. Vials and Isojects®

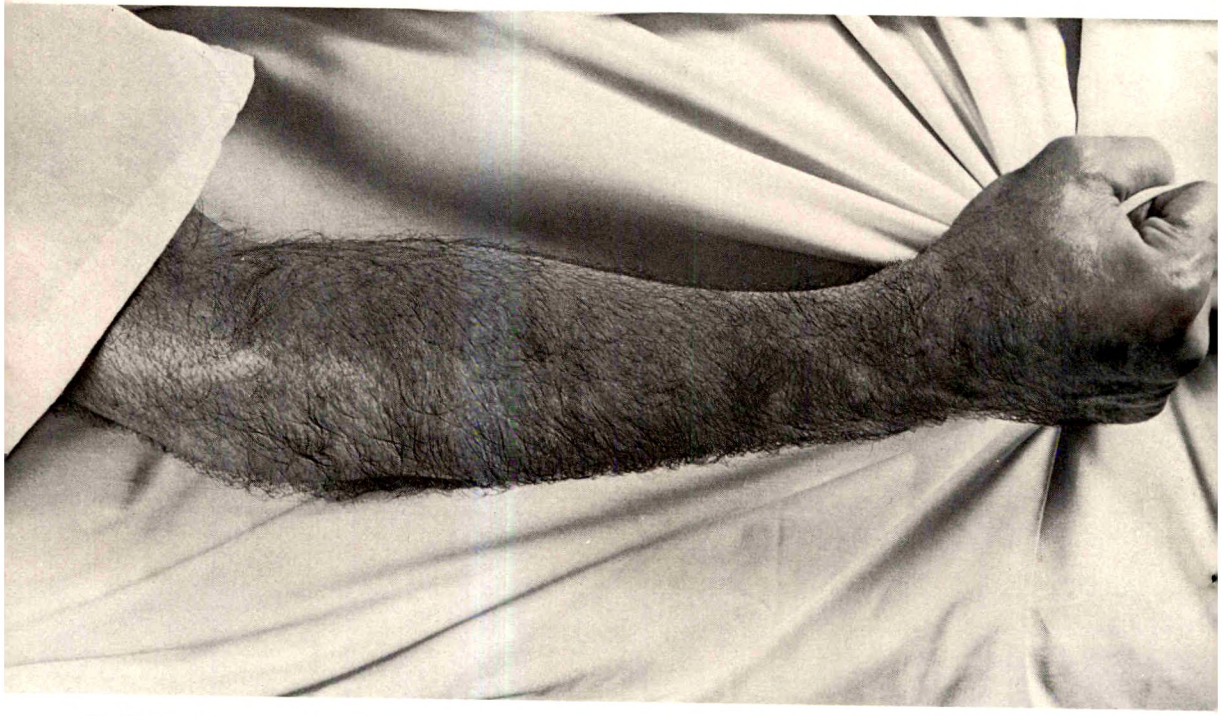
Pfizer
LABORATORIES DIVISION
PFIZER INC.

Please see Brief Summary on following page for contraindications, precautions and adverse reactions.

Vistaril® I.M.
(hydroxyzine HCl)

100 mg./2 ml., 50 mg./ml. and 25 mg./ml.
Vials and Isojects®

Calm
Before Anesthesia... In Recovery



Brief Summary
VISTARIL® (hydroxyzine hydrochloride) Intramuscular Solution
For Intramuscular Use Only

Contraindications: Hypersensitivity to hydroxyzine. The solution for intramuscular use *must not* be injected subcutaneously, intra-arterially, or intravenously.

Hydroxyzine, when administered to the pregnant mouse, rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate. Until adequate data are available to establish safety in early pregnancy, hydroxyzine is contraindicated during this period.

Precautions: *Hydroxyzine may potentiate the action of central nervous system depressants such as narcotics and barbiturates.* In conjunctive use, dosage for these drugs should be decreased as much as 50%. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery. The usual precautions for intramuscular injection should be followed; soft-tissue reactions have rarely been reported when proper technique has been used.

Hydroxyzine intramuscular solution should be injected well within the body of a relatively large muscle. In adults, the preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus), or the mid-lateral thigh. In children, preferably the mid-lateral muscle of the thigh. In infants and small children, the upper outer quadrant of the gluteal region should only be used when necessary, as in burn patients, in c to minimize the possibility of damage to the sciatic nerve. The deltoic area should be used only if well developed, such as in certain adults older children, and only with caution to avoid radial nerve injury. Injections should not be mac'e in the lower and middle thirds of the upper arm. Aspiration is necessary to help avoid intravascular inject

Adverse Reactions: Drowsiness may occur; if so, it is usually transit and may disappear in a few days of continued therapy or upon dosag reduction. Dryness of the mouth may occur with higher doses. Involu tary motor activity, including rare instances of tremor and convulsion has been reported, usually with higher than recommended dosage.

Supply: Vistaril (hydroxyzine HCl) Intramuscular Solution: 25 mg./n 10 ml. vial; 50 mg./ml.—2 ml. and 10 ml. vial; Isoject®, 25 mg./ml. ar 50 mg./ml., 1 ml. fill; 100 mg./2 ml., 2 ml. fill.

Military Depot: NSN 6505-00-052-1367 (50 mg./ml., 10 ml. vial)
VA Depot: NSN 6505-00-052-1367B (50 mg./ml., 10 ml. vial)

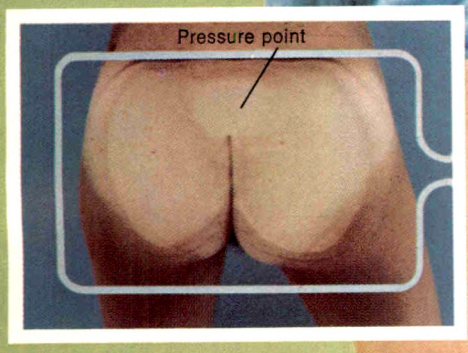
Electrosurgical burn hazard: unsafe current densities created by pressure points.



Subject viewed through transparent plastic.

Remedy: Ground the patient using the American Electro·Surgical Grounding Pad system.

When grounding a patient with a conventional metal dispersive plate, bony protuberances can create pressure points which result in uneven patient contact. Any pressure point can become the site of burn-inducing high current densities.

The American Electro-Surgical Grounding Pad virtually eliminates the hazards associated with pressure points because it replaces patient-to-metal contact with a column of low impedance gel: This non-metal, *non-pressure* interface between patient and grounding device is efficient and reliable.

And since the Grounding Pad does away with patient-to-metal contact, it eliminates many of the other hazards associated with metal grounding devices—hazards such as bent corners and irregularities in the conductive surface.

- The Grounding Pad is pregelled, self-adhering and disposable, so it is as convenient to use as it is reliable.

In the few short years since its introduction, the American Electro-Surgical Grounding Pad system has been chosen over dispersive plates for more than 6,000,000 electrosurgical procedures.

A clinical trial will demonstrate why.

Please contact your American Hospital Supply or NDM representative for a clinical trial, including a total inservice, for your evaluation of the American Electro-Surgical Grounding Pad system.

For a comprehensive booklet describing the Electro-Surgical Grounding Pad system, please write to: NDM Department D, 3040 East River Road, Dayton, Ohio 45439.

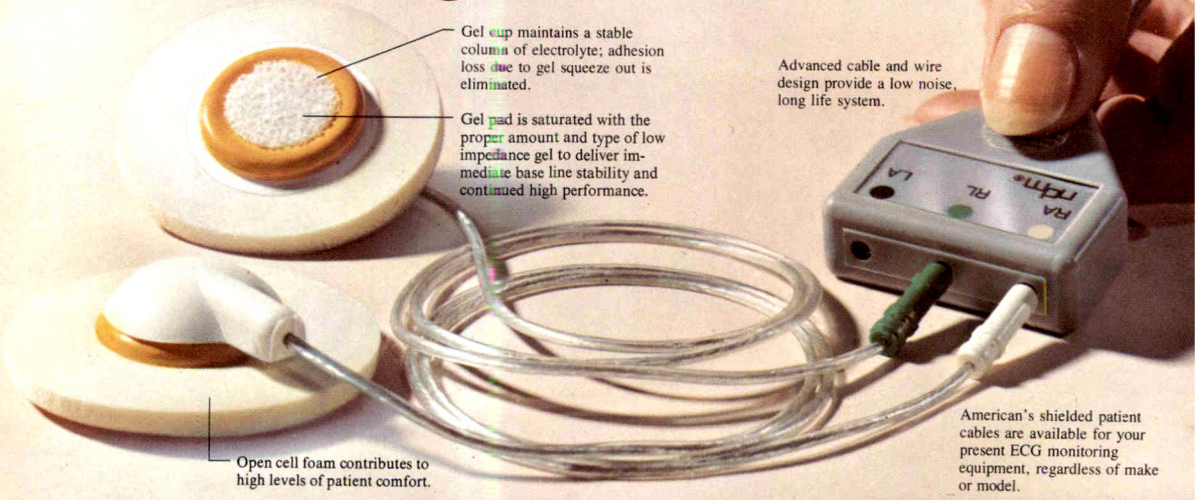
American's O.R. Electrode System brings highest performance to your operating and recovery room ECG monitoring.



So-called "all-purpose" electrodes are bound to have built-in compromises. That's why American offers a full line of ECG monitoring electrodes, each designed for specific applications.

The O.R. Electrode is engineered to answer the special needs of short term monitoring—in operating and recovery rooms—wherever electrode performance can't be compromised.

Pregelled and self-adhering, the O.R. Electrode is applied quickly and delivers a strong signal with immediate base line stability.

The gel cup prevents adhesion loss due to gel squeeze out. The mild electrolyte and soft foam construction virtually eliminate patient discomfort.

Best of all, this advanced electrode is fully compatible with your present ECG equipment. With the appropriate American leadwire and cable, you can enjoy the reliability of an electrode system built with one purpose in mind: To bring the highest ECG monitoring performance to your operating and recovery rooms.

A clinical trial will show why American's O.R. Electrode system is the logical choice for your short term monitoring requirements.

Please contact your American Hospital Supply or NDM representative to arrange a no obligation clinical trial, including a total inservice for your staff. American will supply electrodes, leadwires and cables to adapt to your present monitoring units during the trial period.

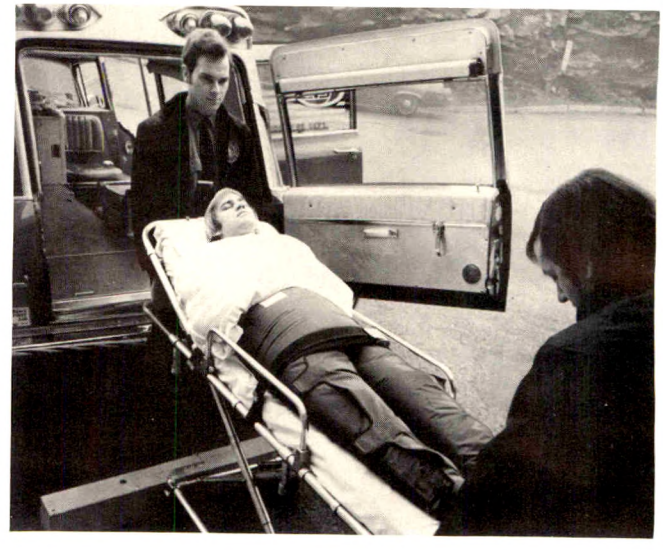
David Clark Company, Medical Products Division, have a new medical anti-shock trouser for pre-hospital trauma treatment. Application of external circumferential pressure results in the autotransfusion of pooled venous blood from below the diaphragm, and, it is claimed, reduces the volume returned to the lower extremities.



★ ★ ★

A new fully automatic clinical blood pressure machine with digital readouts for blood pressure and heart rate has been developed by Med Data, Inc., Madison, Wisconsin.

Designated the MDI-410, the device is stated to have the accuracy of 3 millimeters of mercury, and can be operated in a manual or automatic cycle mode. Both digital and analog outputs are available for connection to a computer or chart recorder for data logging.

A unique electronic circuit simulates the threshold discrimination capabilities of the human ear. The sounds are detected in the cuff around the subject's arm, by a special microphone, and sent to electronic circuits for processing. A small computer analyzes the sounds and the time between them to verify that they are truly Korotkoff sounds.

The Bartlett-Edwards Incentive Spirometer, designed to encourage voluntary sustained maximal inspiration, is now available from McGaw Laboratories, Irvine, California.

The Spirometer encourages inhaling to the maximum lung volume without the swallowing of air. Also, the airway/pleural pressure gradients favor complete alveolar inflation.

Patient discomfort is minimal and cardiac output is not decreased. The patient's number of inspirations is recorded automatically on the unit's indicator.

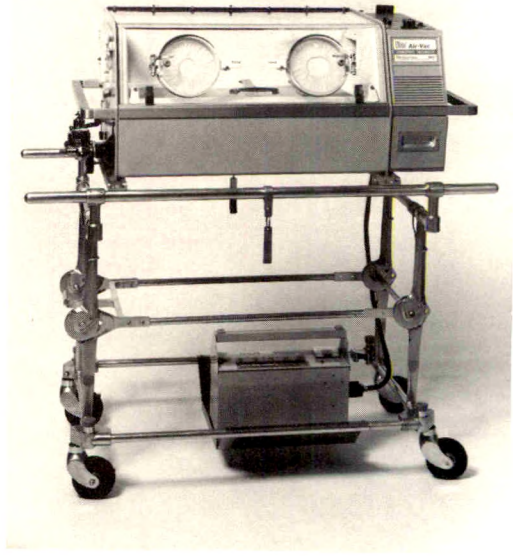
Ohio Medical Products, Madison, Wisconsin, has available the AIR-VAC Transport Incubator—a self-sustaining incubator capable of providing intensive care transportation for the premature and critically-ill newborn. One of the primary requirements of the transport incubator is the ability to convey an infant in complete safety under what mode of transportation is necessitated —air, helicopter, or ambulance.

The AIR-VAC Transport Incubator meets the requirements of the Safe Current Limits Standard of the Association for the Advancement of Medical Instrumentation in regard to leakage current.

The AIR-VAC Transport Incubator is capable of operating from any one of four sources of electrical power: 12 Volt DC (automotive), 24 Volt DC (aircraft), 120 Volt AC 50-400 Hz (wall outlet, helicopter or aircraft) or its own 12 Volt DC Battery Pak. (A model designed for 220/240 Volt, 50-400 Hz is available for foreign markets.) Heat is thermostatically controlled, and filtered air is humidified to the 40-60% comfort range from the humidity reservoir with disposable sponge.



The MONOJECT Sterile "Mini" Continuous Epidural Anesthesia Kit from Sherwood Medical Industries, St. Louis, Missouri, features the MONOJECT Hustead Needle with a point designed to accurately direct the catheter into the epidural space.

The new MONOJECT kit includes a radiopaque Teflon catheter with an exclusive luer lock tube connector to replace the blunt needle usually used to link the catheter to the syringe containing anesthetic. The connector eliminates splitting of the catheter that sometimes occurs with a blunt needle, and has a clear hub to allow an aspiration test for blood to assure correct catheter placement.

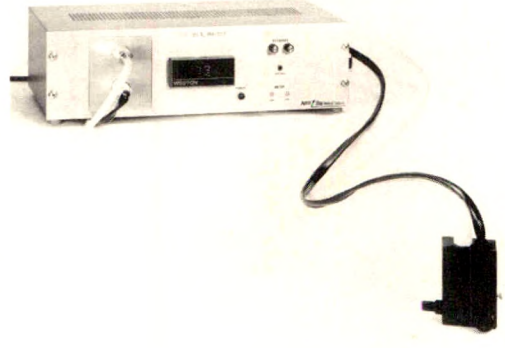
The catheter has five cm graduations from the distal end, and the tip is marked with a zero to give the user a positive check for complete catheter removal. The cap from the luer lock tip connector serves as a luer lock plug in continuous administration procedures.

★ ★ ★

Ohio Medical Products, Madison, Wisconsin, has introduced the Model 720 Nitrogen Gas Analyzer with a specially designed remote sample head.

This new Ohio pulmonary function instrument incorporates a miniaturized gas spectrometer with computer-type linearization circuits to provide usable output signals. An illuminated digital display provides the operator with direct readout of nitrogen concentration to one decimal place with a readout accuracy of 0.1%.

The remote sample head, which is placed near the patient's mouth, continuously draws samples of gas entering and leaving the patient's mouth. Minimum dead space and maximum structural solidarity assure rapid response and repeatable test results. Absolute linearity over an operating range of nitrogen concentration from 2% to 85% is provided through specially designed circuitry in the solid state electronics.



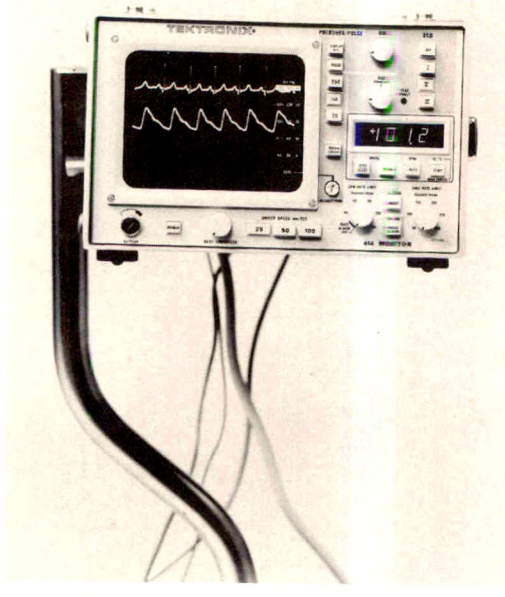
★ ★ ★

The report, "Development and Evaluation of Methods for the Elimination of Waste Anesthetic Gases and Vapors in Hospitals," outlines effective control procedures for eliminating waste anesthetic gases in operating rooms.

This publication, GPO Stock Number 017-033-00071, is available from the Superintendent of Documents, US Government Printing Office, Washington DC 20402. The cost is $2.15 each.

Robertshaw Controls Company, Anaheim, California, announces a new flow selector valve with certain advantages over the commonly used flow meter. It does not have to be mounted vertically but will function accurately in any position. Any of the five flow selections can be dialed easily and quickly.

★ ★ ★



Tektronix®, Beaverton, Oregon, has a new 414 portable patient monitor, featuring digital display of heart rate, systolic/diastolic blood pressures, mean blood pressure and temperature, which increases the monitoring capability of anesthesiologists in the operating room and recovery room. The 414 also gives dual-trace crt display of ECG and blood pressure or peripheral pulse.

Since it can measure mean, as well as arterial, venous, and pulmonary wedge pressures, the 414 adds more complex applications, such as cardiac catheterization, to the realm of portable monitors. Digital readout enhances both accuracy and convenience of measurements.

It also features pulse pressure and heart rate alarms, selectable pressure ranges and sweep speeds, and internal battery pack for cordless operation.

PRECISE, ECONOMICAL, SAFE...

RALS POWER UNIT

...INSTANT ATOMIZATION FOR FAST TOPICAL ANESTHESIA

Fast, measured topical anesthesia is ready at your finger tips in a Rals Power Unit. Forget about pumping bulbs, uneven atomization, and limited spraying duration. The Rals Power Unit uses a non-toxic propellant, dichlorodifluoromethane (freon) to activate standard DeVilbiss Atomizers No's. 151, 152 and 163. Instantly, a fine mistlike spray is produced. A graduated solution vial is available for measuring the amount of solution administered.

The Rals Power Unit has been proven effective in cocainization prior to endotracheal intubation, endoscopic instrumentation, laryngotracheal insufflation, and in a variety of nose and throat procedures.

Rals Power Unit #168 are supplied six to a box with adaptor top and metal base. Illustration shows #152 atomizer. All styles in stock.

PEDIATRIC ANESTHESIOLOGY RESIDENCY

Childrens Hospital of Los Angeles

Three-phase program: Clinical, Academic, Investigative, emphasizing practical aspects of anesthesiology related to infants and children.

AMA approval for third-year residency. Positions available from two months to one year.

Apply: George B. Lewis, Jr., M.D.
Head, Division of Anesthesiology
Childrens Hospital of Los Angeles
4650 Sunset Boulevard
Los Angeles, California 90054
Phone (213) 660-2450, Ext. 2262

APPROVED THREE-YEAR ANESTHESIOLOGY RESIDENCY

Available July 1, 1976, in 620-bed, active general hospital, pain clinic, over 12,000 anesthetic procedures annually. Training in all phases of anesthesiology and resuscitation including modern recovery unit, acute cardiopulmonary medicine, computer sciences (if requested) and clinical research, coronary care, intensive care facility and neonatal unit. Special emphasis placed upon regional and conduction anesthesia. First year annual stipend $9,450 plus maintenance and modern apartments close to hospital. Apply for further particulars to: P. C. Lund, M.D., Director, Department of Anesthesiology, Conemaugh Valley Memorial Hospital, Johnstown, Pennsylvania 15905.

ANESTHESIOLOGY—66-man medical group located next to modern, accredited 480-bed hospital seeks Board Certified anesthesiologist to join two associates. Located in upper midwest university metropolitan area of 105,000; 35 minutes from superb clean lake region; associated with four-year medical school, teaching opportunities available; salary open; all specialties represented; will pay travel expenses for physician and spouse for interview. Write Box 11-75-A in care of I.A.R.S.

FACULTY POSITIONS

Department of Anesthesiology, Charity Hospital, New Orleans, affiliated with LSU and Tulane Medical Schools, has three faculty positions open for board certified/eligible anesthesiologists at Associate-Assistant Professor, Instructor levels. Duties involve teaching, research, clinical supervision. Salaries negotiable. Send inquiries and curriculum vitae to: M. Naraghi, M.D., Director, Department of Anesthesiology, Charity Hospital, New Orleans, Louisiana 70140.

CARDIAC ANESTHESIOLOGY FELLOWSHIP

Applications are invited for the period of July 1976 to June 1977 as a third year of anesthesiology training at the Health Center of the University of Pittsburgh. The successful applicant will become a team member in the provision of anesthesia and life support for patients undergoing open heart surgery and will have ample opportunity to pursue research interests at the clinical and laboratory level. For further details apply to:

Malcolm D. Orr, M.B., B.S., Ph.D.
Director of Cardiovascular Anesthesia
Department of Anesthesiology and Critical Care Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania 15213

CHIEF OF ANESTHESIA—Opportunity for developing exclusive anesthesia group services and educational programs for 480-bed JCAH hospital with teaching program and university affils. In West Georgia city of 250,000 approx. 90 miles near Atlanta. Arrangements negotiable. Write Box 11-75-B in care of I.A.R.S.

WANTED IMMEDIATELY — Full-time and part-time Anesthesiologists for positions at small private hospital in Queens, N.Y. Salary competitive. Contact Box 11-75-C in care of I.A.R.S.

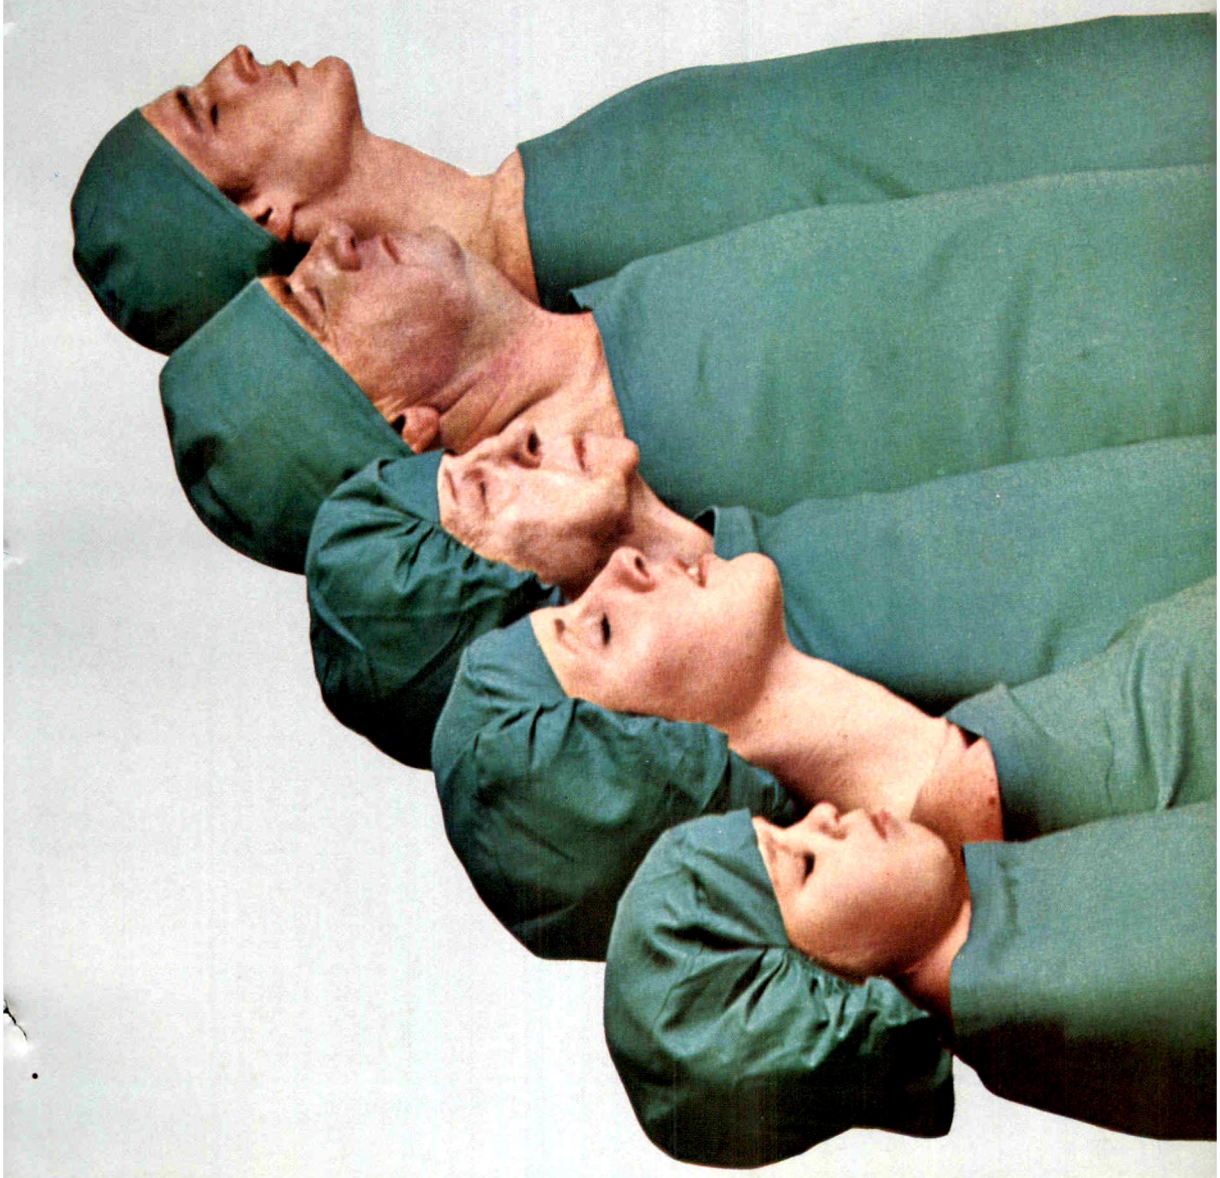
Clinically proven
nondepolarizing muscle relaxant

PAVULON®
pancuronium bromide

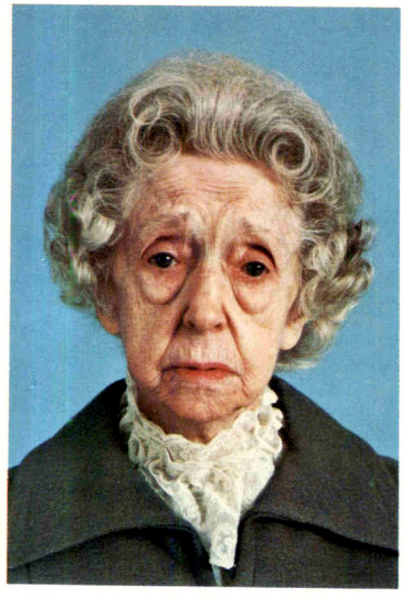
for many patients
for many reasons

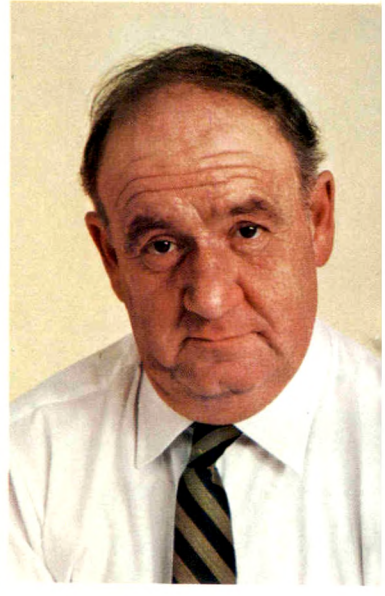


Please turn page for full prescribing information

An unusually fast-acting nondepolarizing blocking agent [1-5]

PAVULON®
pancuronium bromide





for many patients for many reasons

in pediatric surgery[6-12]

Pavulon® has been used with satisfactory results in pediatric patients undergoing elective surgery[11], abdominal surgery[7] and cardiovascular surgery[8]. Dose response studies indicate that, except for neonates, dosage is the same as for adults. In neonates, a test dose of 0.02 mg/kg is recommended to determine responsiveness.

in geriatric surgery[13]

Pavulon® can be considered a preferred relaxant for major surgical procedures in the aged patient because of the relative absence of significant side effects.

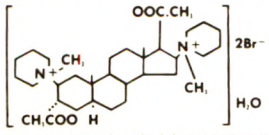
in the high risk patient[2-5, 14-18]

Pavulon® is often preferred for poor risk patients[5,14,16] especially those with asthma or chronic bronchitis[2,14,16,17], cardiovascular disease[4,5,16,18] and patients undergoing abdominal, thoracic or other major surgery[2,5], including open heart surgery[15]. Caution should be exercised, however, in the presence of renal disease since a major portion of the administered drug is excreted unchanged in the urine.

PAVULON® (pancuronium bromide)

THIS DRUG SHOULD ONLY BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.

DESCRIPTION: Pavulon (pancuronium bromide) is the aminosteroid 2 beta, 16 beta-dipiperidine-5 alpha-androstane-3 alpha, 17 beta-diol diacetate dimethobromide. It has the following structural formula:



ACTIONS: Pavulon is a non-depolarizing neuromuscular blocking agent possessing all of the characteristic pharmacological actions of this class of drugs (curariform) on the myoneural junction.

Pavulon is approximately 5 times as potent as d-tubocurarine chloride.

The onset and duration of action of Pavulon is dose dependent. With the administration of 0.04 mg. per kg. the onset of action, as measured by a peripheral nerve stimulator, is usually within 45 seconds, and its peak effect is usually within 4½ minutes; recovery to 90% of control twitch height usually takes place in less than one hour. Larger doses, more suitable for endotracheal intubation, such as 0.08 mg. per kg. of Pavulon have an onset of action of about 30 seconds, and a peak effect within 3 minutes. Supplemental incremental doses of Pavulon, following the initial dose, slightly increase the magnitude of blockade, and significantly increase the duration of the blockade.

Pavulon has little effect upon the circulatory system. The most frequently reported observation is a slight rise in pulse rate.

Human histamine assays, and clinical observations, as well as in *vivo* guinea pig testing, and in *vitro* mast cell testing, indicate that histamine release rarely, if ever, occurs.

Pavulon is antagonized by acetylcholine, anticholinesterases, and potassium ion. Its action is increased by inhalational anesthetics such as halothane, diethyl ether, and methoxyflurane, as well as quinine, magnesium salts, hypokalemia, some carcinomas, and certain antibiotics such as neomycin, streptomycin, kanamycin, and bacitracin. The action of Pavulon may be altered by dehydration, electrolyte imbalance, acid-base imbalance, renal disease, and concomitant administration of other neuromuscular agents.

Pavulon has no known effect on consciousness, the pain threshold, or cerebration.

INDICATIONS: Pavulon is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may also be employed to facilitate the management of patients undergoing mechanical ventilation.

CONTRAINDICATIONS: Pavulon is contraindicated in patients known to be hypersensitive to the drug or to the bromide ion.

WARNINGS: PAVULON SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS, WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION.

In patients who are known to have myasthenia gravis small doses of Pavulon may have profound effects. A peripheral nerve stimulator is especially valuable in assessing the effects of Pavulon in such patients.

USAGE IN PREGNANCY: The safe use of pancuronium bromide has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards. There are insufficient data to support safe use of Pavulon in obstetrics, so such use is not recommended.

PRECAUTIONS: Although Pavulon has been used successfully in many patients with pre-existing pulmonary, hepatic, or renal disease, caution should be exercised in these situations. This is particularly true of renal disease since a major portion of administered Pavulon is excreted unchanged in the urine.

ADVERSE REACTIONS: Neuromuscular: The most frequently noted adverse reactions consist primarily of an extension of the drug's pharmacological actions beyond the time period needed for surgery and anesthesia. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle relaxation resulting in respiratory insufficiency or apnea. Inadequate reversal of the neuromuscular blockade by anticholinesterase agents has also been observed with Pavulon (pancuronium bromide) as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate.

Cardiovascular: A slight increase in pulse rate is frequently noted.

Gastrointestinal: Salivation is sometimes noted during very light anesthesia, especially if no anticholinergic premedication is used.

Skin: An occasional transient rash is noted accompanying the use of Pavulon.

Respiratory: One case of wheezing, responding to deepening of the inhalational anesthetic, has been reported.

DRUG INTERACTION: The intensity of blockade and duration of action of Pavulon is increased in patients receiving potent volatile inhalational anesthetics such as halothane, diethyl ether, enflurane, and methoxyflurane. No increase in intensity of blockade or duration of action of Pavulon is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol.

Prior administration of succinylcholine, such as that used for endotracheal intubation, enhances the relaxant effect of Pavulon and the duration of action. If succinylcholine is used before Pavulon, the administration of Pavulon should be delayed until the succinylcholine shows signs of wearing off.

DOSAGE AND ADMINISTRATION: Pavulon should be administered only by or under the supervision of experienced clinicians. DOSAGE MUST BE INDIVIDUALIZED IN EACH CASE. The dosage information which follows has been derived from dose-response studies based on body weight and is intended to serve as a guide only. Since potent inhalational agents or prior administration of succinylcholine enhance the intensity of blockade and duration of Pavulon (see DRUG INTERACTION), these factors should be taken into consideration in selection of initial and incremental dosage.

In adults the initial intravenous dosage range is 0.04 to 0.1 mg. per kg. Later incremental doses starting at 0.01 mg. per kg. may be used. These increments slightly increase the magnitude of the blockade, and significantly increase the duration of blockade, because a significant number of myoneural junctions are still blocked when there is clinical need for more drug.

If Pavulon is used to provide skeletal muscle relaxation for endotracheal intubation, doses of 0.06 to 0.1 mg. per kg. are recommended. Conditions satisfactory for intubation are usually present within 2 to 3 minutes. The ability of the anesthetist to intubate with Pavulon (pancuronium bromide) improves with experience.

Dosage in Children: Dose-response studies in children indicate that, with the exception of neonates, dosage requirements are the same as for adults. Neonates are especially sensitive to nondepolarizing neuromuscular blocking agents, such as Pavulon, during the first month of life. It is recommended that a test dose of 0.02 mg. per kg. be given first in this group to measure responsiveness.

MANAGEMENT OF PROLONGED NEUROMUSCULAR BLOCKADE: Residual neuromuscular blockade beyond the time period needed for surgery and anesthesia may occur with Pavulon as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade. Under such circumstances the primary treatment is manual or mechanical ventilation and maintenance of a patent airway until complete recovery of normal respiration is assured. Regonol® (pyridostigmine bromide) or neostigmine, in conjunction with atropine, will usually antagonize the skeletal muscle relaxant action of Pavulon. These should be accompanied by or preceded by injection of atropine sulfate to minimize the incidence of cholinergic side effects, notably excessive secretions and bradycardia. Satisfactory reversal can be judged by adequacy of skeletal muscle tone, and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of twitch height. Failure of prompt reversal (within 30 minutes) may occur in the presence of extreme debilitation, carcinomatosis, and with concomitant use of certain broad spectrum antibiotics, or anesthetic agents and adjuncts which enhance neuromuscular blockade or cause respiratory depression of their own. Under such circumstances the management is the same as that of prolonged neuromuscular blockade; ventilation must be supported by artificial means until the patient has resumed control of his respiration. Prior to the use of reversal agents, reference to the specific package insert of the reversal agents should be made.

CAUTION: Federal law prohibits dispensing without prescription.

HOW SUPPLIED:

2 ml. ampuls—2 mg./ml.—box of 25
5 ml. ampuls—2 mg./ml.—box of 25
10 ml. multiple dose vials—1 mg./ml.—box of 25

Organon Inc.
West Orange, N. J. 07052

The tender touch

These soft, pliable blood pressure cuffs are ideal for use on newborns and infants. Incorporating a Latex bladder, minimizing any chances for skin irritation, and Silicon wrap-around with 12-inch inflating tube. They are secured by the Velcro hook and pile method, with no eyes to hook nor ends to tuck in. They are instantly peeled apart for easy removal.

Cuffs are available in two sizes:
22080 - 1⅜ x 5" (new born)
22081 - 2¼ x 6" (infant)

For additional information write for brochure number 27.

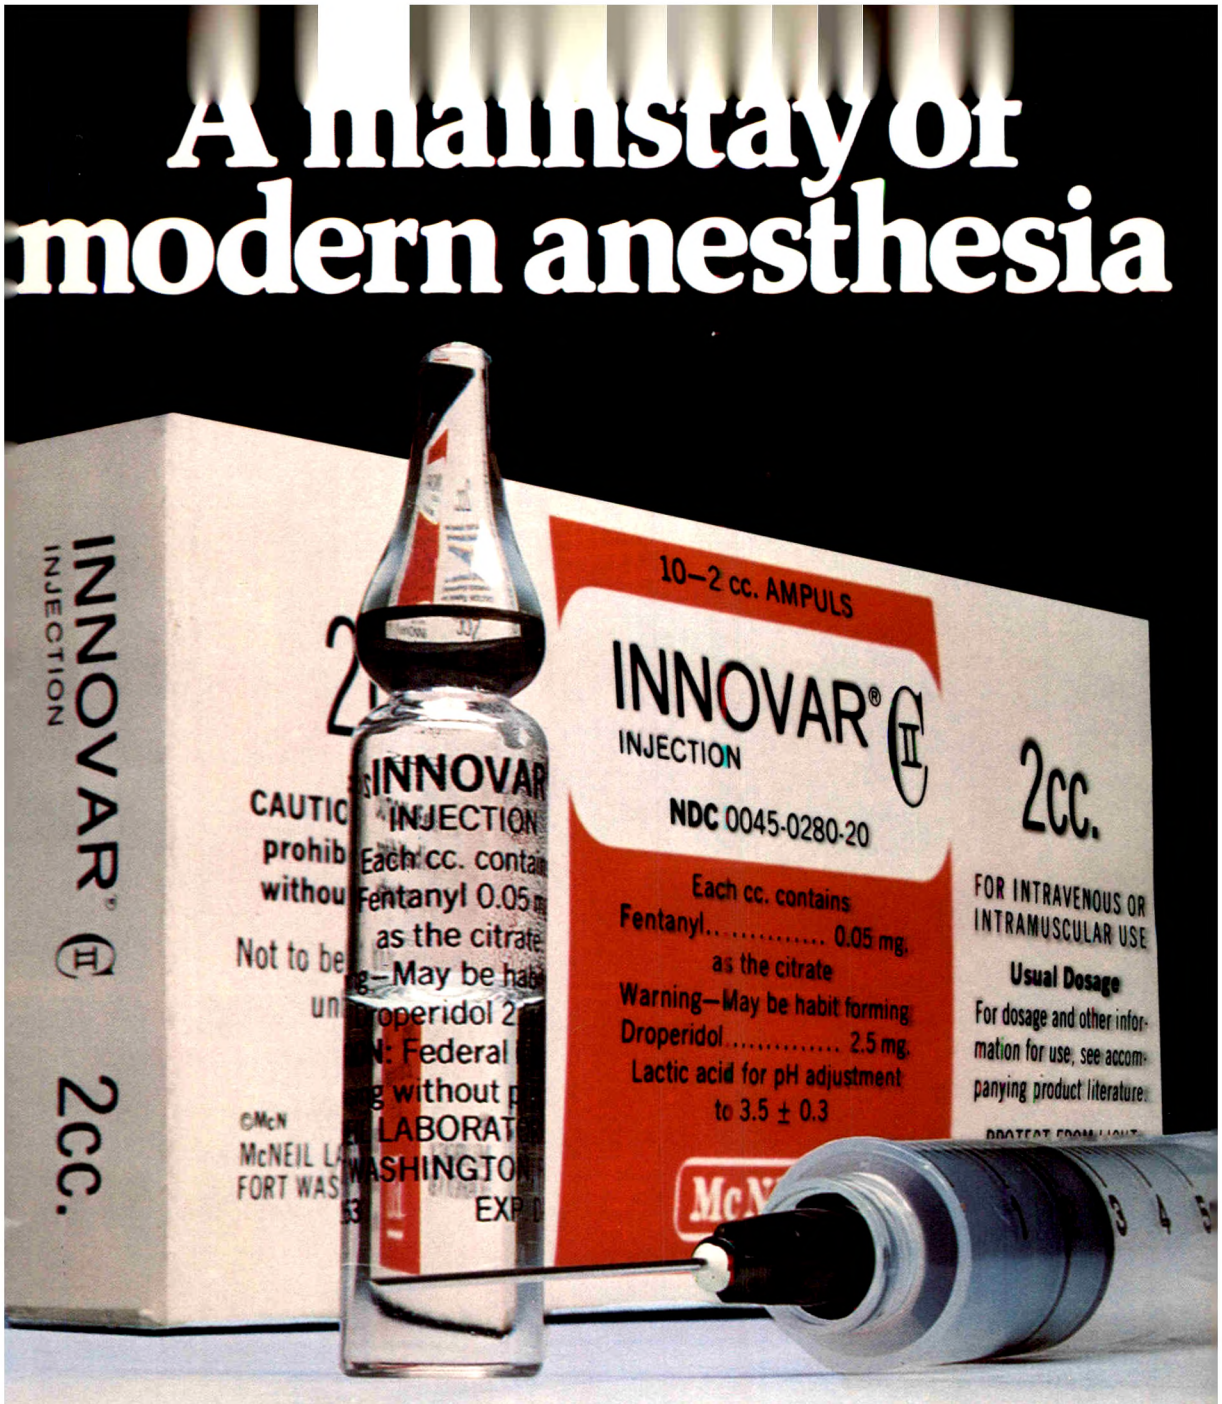
A mainstay of modern anesthesia



- As an adjunct to general anesthesia
- As a supplement to regional anesthesia
- Used without a general anesthetic in certain diagnostic procedures

INNOVAR® injection is available for use only upon direction of a physician.

Special educational material available

A Programmed Instruction Manual on the chemistry, pharmacology and clinical applications of INNOVAR injection and its components is available from McNeil Laboratories. For further information, please write: Medical Dept., McNeil Laboratories, Inc., Fort Washington, Pa. 19034, Attn: Robert T. McSherry, M.D.

Innovar® injection (C)

The two components of INNOVAR® injection, fentanyl and droperidol, have different pharmacologic actions. Before administering INNOVAR injection, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action.

DESCRIPTION

Each cc. contains (in a 1:50 ratio):

Fentanyl ..... 0.05 mg.
as the citrate

Warning: May be habit forming

Droperidol ..... 2.5 mg.
Lactic acid for adjustment of pH to 3.5± 0.3

FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY

Protect from Light

ACTIONS INNOVAR injection is a combination drug containing a narcotic analgesic, fentanyl, and a neuroleptic (major tranquilizer), droperidol. The combined effect, sometimes referred to as neuroleptanalgesia, is characterized by general quiescence, reduced motor activity, and profound analgesia; complete loss of consciousness usually does not occur from use of INNOVAR injection alone. The incidence of early postoperative pain and emesis may be reduced.

A. Fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. Fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. Fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays, and skin wheal testing in man, as well as *in vivo* testing in dogs indicate that histamine release rarely occurs with fentanyl.

Fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours. Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics, it may be considerably longer than the analgesic effect.

B. Droperidol produces marked tranquilization and sedation. It also produces an antiemetic effect as evidenced by the antagonism of apomorphine in dogs. It potentiates other CNS depressants. It also produces mild alpha adrenergic blockade, peripheral vascular dilatation and reduction of the pressor effect of epinephrine. Droperidol can produce hypotension and decreased peripheral vascular resistance. It may decrease pulmonary arterial pressure (particularly if it is abnormally high). It may reduce the incidence of epinephrine-induced arrhythmias but it does not prevent other cardiac arrhythmias. The onset of action is from three to ten minutes following intravenous or intramuscular administration. The full effect, however, may not be apparent for 30 minutes. The duration of the sedative and tranquilizing effects generally is two to four hours. Alteration of consciousness may persist as long as 12 hours. This is in contrast to the much shorter duration of action of fentanyl.

INDICATIONS INNOVAR injection is indicated to produce tranquilization and analgesia for surgical and diagnostic procedures. It may be used as an anesthetic premedication, for the induction of anesthesia, and as an adjunct in the maintenance of general and regional anesthesia. If the supplementation of analgesia is necessary, SUBLIMAZE® (fentanyl) injection alone rather than the combination drug INNOVAR injection should usually be used.

CONTRAINDICATIONS INNOVAR injection should not be used in patients who are hypersensitive to either component.

WARNINGS PATIENTS WHO HAVE RECEIVED *INNOVAR* INJECTION SHOULD BE UNDER APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

The respiratory depressant effect of narcotics persists longer than their measured analgesic effect. When used with INNOVAR injection, the total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, be used initially in reduced doses, as low as 1/4 to 1/3 those usually recommended.

INNOVAR injection may cause muscle rigidity, particularly involving the muscles of respiration. This effect is due to the fentanyl component and is related to the speed of injection. Its incidence can be reduced by the use of slow intravenous injection. Once the effect occurs it is managed by the use of assisted or controlled respiration and by a neuromuscular blocking drug, if necessary.

FLUIDS AND OTHER COUNTERMEASURES TO MANAGE HYPOTENSION SHOULD ALSO BE AVAILABLE.

Drug Dependence: *Fentanyl, the narcotic analgesic component, can produce drug dependence of the morphine type and therefore has the potential for being abused.*

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl, in this regard, has not been established, the use of INNOVAR injection or SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: INNOVAR injection should be used with caution in patients who may be particularly susceptible to respiratory depression such as comatose patients who may have a head injury or brain tumor. In addition, these drugs may obscure the clinical course of patients with head injury.

Usage in Children: The safety of INNOVAR injection in children two years of age or younger has not been established.

Usage in Pregnancy: The safe use of INNOVAR injection has not bee established with respect to possible adverse effects upon fetal developmen

Therefore, it should be used in women of childbearing potential only when, in tl judgment of the physician, the potential benefits outweigh the possible hazard There are insufficient data regarding placental transfer and fetal effect therefore, safety for the infant in obstetrics has not been established.

PRECAUTIONS *The initial dose of INNOVAR injection should be appropri ly reduced in elderly, debilitated and other poor risk patients. The effect of t initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and sor peridural anesthetics, can alter respiration by blocking intercostal nerves, and c cause peripheral vasodilatation and hypotension because of sympathet blockade. Through other mechanisms (see Actions) fentanyl and droperidol al depress respiration and blood pressure. Therefore, when INNOVAR injection used to supplement these forms of anesthesia, the anesthetist must be famili with the physiological alterations involved, and be prepared to manage them the patients selected for this form of anesthesia.

The droperidol component of INNOVAR injection may decrease pulmonar arterial pressure. This fact should be considered by those who conduct diagnost or surgical procedures where interpretation of pulmonary arterial pressu measurements might determine final management of the patient.

Vital signs should be monitored routinely.

INNOVAR injection, and SUBLIMAZE fentanyl, should be used with cautio in patients with chronic obstructive pulmonary disease, patients with decrease respiratory reserve, and others with potentially compromised ventilation. In suc patients narcotics may additionally decrease respiratory drive and increa airway resistance. During anesthesia this can be managed by assisted c controlled respiration. Postoperatively respiratory depression caused b narcotic analgesics can be reversed by narcotic antagonists (levallorphar nalorphine, and naloxone); consult individual prescribing information befo using.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, an general anesthetics) have additive or potentiating effects with INNOVA injection. When patients have received such drugs, the dose of INNOVA injection required will be less than usual. Likewise, following the administratio of INNOVAR injection the dose of other CNS depressant drugs should b reduced.

INNOVAR injection should be administered with caution to patients with live and kidney dysfunction because of the importance of these organs in th metabolism and excretion of drugs.

If hypotension occurs, the possibility of hypovolemia should be considered an managed with appropriate parenteral fluid therapy. Repositioning the patient t improve venous return to the heart should be considered when operativ conditions permit. It should be noted that in spinal and peridural anesthesia tilting the patient into a head down position may result in a higher level o anesthesia than is desirable, as well as impair venous return to the heart. Car should be exercised in the moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus these other countermeasures do not correct the hypotension, then the administration o pressor agents other than epinephrine should be considered. Epinephrine may paradoxically decrease the blood pressure in patients treated with INNOVAR injection due to the alpha-adrenergic blocking action of droperidol.

The fentanyl component may produce bradycardia, which may be treated with atropine; however, INNOVAR injection should be used with caution in patients with cardiac bradyarrhythmias.

When the EEG is used for postoperative monitoring, it may be found that the EEG pattern returns to normal slowly.

ADVERSE REACTIONS The most common serious adverse reactions reporte to occur with INNOVAR injection are respiratory depression, apnea, muscular rigidity, and hypotension; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have beer observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with anti-parkinson agents.

Other adverse reactions that have been reported are dizziness, chills and/or shivering, twitching, blurred vision, hyperactivity on induction, laryngospasm, transient hypertension, nausea and emesis, diaphoresis, emergence delirium, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression).

Postoperative drowsiness is also frequently reported.

OVERDOSAGE ***Manifestations:*** The manifestations of INNOVAR injection overdosage are an extension of its pharmacologic actions.

Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered. A specific narcotic antagonist such as nalorphine, levallorphan or naloxone should be available for use as indicated to manage respiratory depression caused by the narcotic component fentanyl. This does not preclude the use of more immediate countermeasures. Consult the package inserts for the individual narcotic antagonists for details about use.

HOW SUPPLIED INNOVAR® injection is supplied in 2 cc. (**NDC** 0045-0280-20) and 5 cc. (**NDC** 0045-0280-50) ampuls, in packages of 10.

IMPORTANT: Complete dosage information is available in insert which accom panies each package (or on request). The drug is available only upon direction of a physician.

When halothane is the anesthetic of choice...

Now you have a choice of halothanes -

A HIGH PURITY HALOTHANE is now available direct from an experienced producer. For over four years our Canadian subsidiary has been producing and distributing halothane in Canada, Australia, Italy, France, Denmark and elsewhere overseas. For almost two years American military hospitals have been using our halothane, and currently members of many major U.S. hospital purchasing groups have switched to Halocarbon halothane.

Halothane is one of the purest organic compounds made commercially. But a high sensitivity gas chromatograph can draw a graph from which the identity and amount of impurities can be determined. Typical analyses for the Halocarbon and the ICI (Ayerst) products are shown on the right.

Both products are well over 99.99% pure and contain impurities at the ppm level that would be nontoxic at concentrations 10,000 times higher. (1,2)

Our pure product can give you substantial price saving. You may have noticed the drop in the prevailing price last spring when our halothane was first introduced to general use in the United States. Even after that drop our price is about 20% lower. Our consistent high purity plus years of experience in use together give assurance of reliability and your hospital will appreciate our lower prices. So why not ask your pharmacist to request our literature and prices?

A Word about Insert Language

We doubt that many practitioners are aware of the latest version of the Halothane insert. The insert is a published statement of the generally accepted methods of use. Because it can be revised and because important revisions are done by "blue ribbon" committees of anesthesiologists the insert carries much greater authority than journal articles. And consequently the precise wording of the insert looms very large in malpractice cases.

There has been an important change recently in our insert wording. As a result of a more careful evaluation of halothane data, the following sequence appears in our new insert under Warnings:

When a previous exposure to Halothane U.S.P. was followed by unexplained jaundice, consideration should be given to the use of other anesthetic agents.

Replacing the earlier statement in Contraindications:

Halothane U.S.P. should be avoided when a previous exposure was followed by fever and jaundice, or when there was an unexplained postoperative fever.

This revision makes two fundamental changes in the recommendations regarding exposure to halothane of patients with previous postoperative problems after halothane.

- **It removes "unexplained fever" completely as a contraindication.**
- **It softens considerably the caution against reexposure to halothane when postoperative jaundice followed a previous use.**

Both of these are important changes in a generally accepted statement of prudent practice.

Halothane

U.S.P.

PHYSICAL PROPERTIES OF HALOTHANE

Structure	$CF_3CHBrCl$
Molecular weight	197.4
Boiling Point at 760 mm. of Hg	50.2°C
Specific gravity gas (air=1)	6.8 (calculated)
liquid	1.87
Solubility in 100 parts of water	0.345 parts
Vapor pressure at 20°C	243 mm. of Hg
Blood/gas partition coefficient at 37°C	2.3

DESCRIPTION

Halothane U.S.P. is an inhalation anesthetic which is nonflammable and nonexplosive. When exposed to light this drug decomposes slowly and may form volatile acids. To stabilize the product thymol (0.01% w/w) has been added, and the product packed in colored bottles. Halothane U.S.P. is stable in contact with soda lime. When moisture is present, the vapor attacks aluminum, brass, and lead, but not copper. Halothane U.S.P. is soluble in rubber, some plastics, and similar materials; such materials will deteriorate rapidly in contact with Halothane U.S.P. vapor or liquid.

Thymol accumulates in vaporizers because it is much less volatile than Halothane U.S.P., and in time a yellow color may develop in the wick and remaining liquid. Residual thymol can easily be washed out with a small amount of fresh Halothane U.S.P.

ACTIONS

Halothane U.S.P. is an inhalation anesthetic. Induction and recovery are rapid and depth of anesthesia can be rapidly altered. Halothane U.S.P. progressively depresses respiration. There may be tachypnea with reduced tidal volume and alveolar ventilation. Halothane U.S.P. is not an irritant to the respiratory tract, and no increase in salivary or bronchial secretions ordinarily occurs. Pharyngeal and laryngeal reflexes are rapidly obtunded. It causes bronchodilation. Hypoxia, acidosis, or apnea may develop during deep anesthesia.

Halothane U.S.P. reduces the blood pressure, and frequently decreases the pulse rate and the greater the concentration of the drug, the more evident these changes become. Atropine may reverse the bradycardia. Halothane U.S.P. does not cause the release of catecholamines from adrenergic stores. Halothane U.S.P. also causes dilation of the vessels of the skin and skeletal muscles.

Cardiac arrhythmias may occur during Halothane U.S.P. anesthesia. These include nodal rhythm, AV dissociation, ventricular extrasystoles and asystole. Halothane U.S.P. sensitizes the myocardial conduction system to the action of epinephrine and norepinephrine, and the combination may cause serious cardiac arrhythmias. Halothane U.S.P. increases cerebral spinal fluid pressure. Halothane U.S.P. produces moderate muscular relaxation. Muscle relaxants are used as adjuncts in order to maintain lighter levels of anesthesia. Halothane U.S.P. augments the action of nondepolarizing relaxants and ganglionic blocking agents. Halothane U.S.P. is a potent uterine relaxant.

INDICATIONS

Halothane U.S.P. is indicated for the induction and maintenance of anesthesia.

CONTRAINDICATIONS

Halothane U.S.P. is not recommended for obstetrical anesthesia except when uterine relaxation is required.

WARNINGS

When a previous exposure to Halothane U.S.P. was followed by unexplained jaundice, consideration should be given to the use of other anesthetic agents.

Halothane U.S.P. should be used in vaporizers that permit a reasonable approximation of output, and preferably of the calibrated type. The vaporizer should be placed out of circuit in closed circuit rebreathing systems: otherwise overdosage is difficult to avoid. The patient should be closely observed for signs of overdosage, i. e. depression of blood pressure, pulse rate, and ventilation, particularly during assisted or controlled ventilation.

USAGE IN PREGNANCY: Safe use of Halothane U.S.P. has not been established with respect to possible adverse effects upon fetal development. Therefore, Halothane U.S.P. should not be used in women where pregnancy is possible, and particularly during early pregnancy unless, in the judgment of the physician, the potential benefits outweigh the unknown hazards to the fetus.

PRECAUTIONS

The uterine relaxation obtained with Halothane U.S.P. unless carefully controlled, may fail to respond to ergot derivatives and oxytocic posterior pituitary extract.

Halothane U.S.P. increases cerebrospinal fluid pressure. Therefore, in patients with markedly raised intracranial pressure, if Halothane is indicated, administration should be preceded by measures ordinarily used to reduce cerebrospinal fluid pressure. Ventilation should be carefully assesed, and it may be necessary to assist or control ventilation to insure adequate oxygenation and carbon dioxide removal.

Epinephrine or norepinephrine should be employed cautiously, if at all, during Halothane U.S.P. anesthesia since their simultaneous use may induce ventricular tachycardia or fibrillation.

Nondepolarizing relaxants and ganglionic blocking agents should be administered cautiously, since their actions are augmented by Halothane U.S.P.

ADVERSE REACTIONS

The following adverse reactions have been reported: hepatic necrosis, cardiac arrest, hypotention, respiratory arrest, cardiac arrhythmias, hyperpyrexia, shivering, nausea, and emesis.

DOSAGE AND ADMINISTRATION

Halothane U.S.P. may be administered by the nonrebreathing technic, partial rebreathing, or closed technic. The induction dose varies from patient to patient. The maintenance dose varies from 0.5 per cent to 1.5 per cent.

HOW SUPPLIED

Amber bottles of 125 ml and 250 ml stabilized with 0.01% (w/w) thymol.

CAUTION: FEDERAL LAW (U. S. A.) PROHIBITS DISPENSING WITHOUT PRESCRIPTION

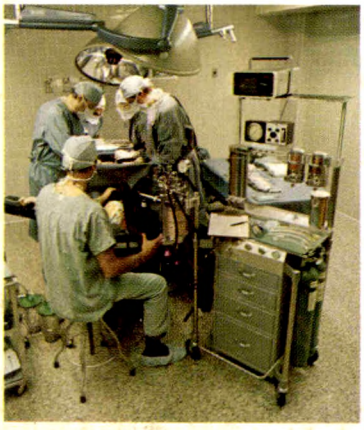
In your hands... the light where you need it.



Light placement. Shaft length. Tip curvature. The largest variety of blade and handle sizes available. Whatever your style preference, there's a Foregger laryngoscope that's just right for you. Choose Miller, MacIntosh, Phillips, Wis-Foregger, Siker, Flagg, Whitehead, Fink, Wis-Hipple, Polio, Guedel, Eversole, Bennett, Bizarri-Guiffrida, or Snow. A full range — each manufactured with quality-designed craftsmanship.

From the routine intubation to the most unusual, Foregger laryngoscope blades help put the light where you need it. For more information, contact your sales representative, Foregger dealer, or write to Air Products and Chemicals, Inc., Medical Products Division, P.O. Box 538, Allentown, Pa. 18105.

ANESTHESIA AND ANALGESIA . . . Current Researches is published bimonthly by the International Anesthesia Research Society, a non-profit scientific and educational corporation of the state of Ohio. Members of the Board of Trustees of the Society are: Kenneth K. Keown, M.D., John T. Martin, M.D., Emerson A. Moffitt, M.D., Dean H. Morrow, M.D., Edwin S. Munson, M.D., B. B. Sankey, M.D., T. H. Seldon, M.D., Robert K. Stoelting, M.D. Emeritus Trustees are: Paul R. Dumke, M.D., Morris J. Nicholson, M.D.

EDITORIAL CORRESPONDENCE and manuscripts should be addressed to: **T. H. Seldon, M.D., Editor, Kahler East—Suite C, Rochester, Minnesota 55901, U.S.A. Telephone: (507) 288-8655.** (See "A Guide for Authors" for information concerning manuscript preparation.) Original articles accepted for publication, or papers presented at the Society's annual scientific meetings which are subsequently published in this Journal become the property of the International Anesthesia Research Society, publisher. Reproduction in whole or in part is not permitted except by written consent of the publisher and the author.

BUSINESS CORRESPONDENCE, including subscription and membership payments, single issue purchases, change of address notices, requests for membership applications, should be sent to: **B. B. Sankey, M.D., Executive Secretary and Business Manager, International Anesthesia Research Society, 3645 Warrensville Center Road, Cleveland, Ohio 44122. Telephones: (216) 295-1124, 295-1130.**

SUBSCRIPTION RATE: $25.00 per year (6 issues), including postage.

MEMBERSHIP DUES: $25.00 per year, includes a subscription to the Journal. **Membership** available to individuals with doctorate degrees in medicine, osteopathy, dentistry, veterinary medicine or other disciplines who are engaged either in active clinical practice of or research in anesthesiology. **Associate Membership** available to individuals certified, licensed or accredited in anesthesia-related professions (CRNA, ARIT, Physician Assistant). **Educational Membership** (two years for $25.00) available to interns, residents, students in nurse anesthesia and related training programs.

SINGLE ISSUES: $4.50 each for years beginning 1970; $3.00 for years 1954-1969; $2.00 for years 1928-1953. (See "Back Issues Available" or write to Cleveland business office for listing.)

REPRINTS: For single copies, write directly to senior author at address listed on title page. Quantity orders (minimum 100) processed through Cleveland business office, prices on request.

MAILING DATES: Journals mailed 25th of January, March, May, July, September and November. Second Class postage paid at Cleveland, Ohio.

CHANGE OF ADDRESS NOTICES: Send to Cleveland business office by first day of the above months to ensure correct addressing of Journals. Replacement copies of missing Journals will be furnished without charge only if original copy is returned by post office as undeliverable.

ADVERTISING: Rate sheets, including advertising clearance procedure, available from national advertising representative: Charles B. Slack, Inc., 6900 Grove Road, Thorofare, New Jersey 08086—Telephone: (609) 848-1000. Orders, contracts, reproduction materials, set copy and classified ad copy should be sent only to Cleveland office.

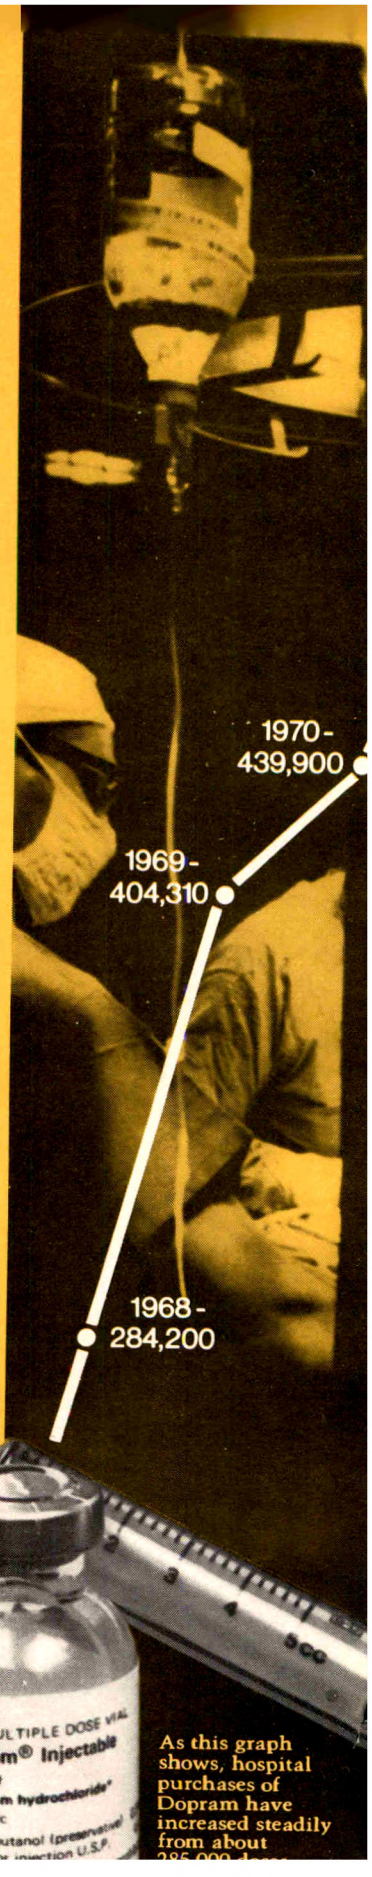
In all types of hospitals across the United States, its usage grows–

Dopram®
Injectable
(doxapram HCl)

Seven years ago, A. H. Robins introduced Dopram, a unique respiratory stimulant developed in the company's research laboratories. What made this drug so useful to the anesthesiologist was its ability to rapidly restore the respiratory drive in patients with drug-induced post anesthetic depression.

Usage of Dopram has been steadily increasing each year, until today it has become a very important drug in the armamentarium of more than 1,500 hospitals of all types in all 50 states, the District of Columbia, and a number of foreign countries. These hospitals purchased more than 600,000 doses in 1972 alone.

Dopram–an important drug in anesthesiology. Try it for sighs!



As this graph shows, hospital purchases of Dopram have increased steadily from about

Indications

1. To stimulate respiration in patients with drug induced post-anesthetic respiratory depression or apnea other than that due to muscle relaxant drugs.
2. To pharmacologically stimulate deep breathing in the so-called "stir-up" regimen in the post-operative patient. Simultaneous administration of oxygen is desirable.
3. To hasten arousal and return of protective pharyngeal and laryngeal reflexes.
4. To aid in the differential diagnosis of post-anesthetic respiratory depression. Failure to adequately stimulate respiration suggests residual muscle relaxant effect.
5. To stimulate respiration, hasten arousal and to encourage the return of laryngopharyngeal reflexes in patients with mild to moderate respiratory and CNS depression due to drug overdosage.

Contraindications—Epilepsy and other convulsive states: incompetence of the ventilatory mechanism due to muscle paresis, flail chest, pneumothorax, airway obstruction, and extreme dyspnea; severe hypertension and cerebrovascular accidents; hypersensitivity.

Doxapram is not recommended for patients 12 years of age or under because studies to evaluate its safety and efficacy have not been performed.

Warnings—Doxapram is an analeptic agent; it is neither an antagonist to muscle relaxant drugs nor a specific narcotic antagonist. Since doxapram has an acid pH, it should not be mixed with alkaline solutions such as thiopental sodium.

Since narcosis may recur after stimulation with doxapram, care should be taken to maintain close observation until the patient has been fully alert for 1/2 to 1 hour. (Duration of drug 5-12 minutes.)

Doxapram is an adjunct to well-accepted supportive measures and resuscitative techniques. It may not stimulate adequate spontaneous breathing or provide sufficient arousal in patients who are severely depressed with CNS depressant drugs.

When doxapram is administered to postoperative patients or to patients in a state of narcosis with chronic pulmonary insufficiency, oxygen should be administered concomitantly. Failure to do so may result in further oxygen debt and more severe dyspnea due to the increased work of breathing.

Doxapram should be administered with great care and only under close supervision to patients with cerebral edema, bronchial asthma, severe tachycardia, cardiac arrhythmia, cardiac disease, hyperthyroidism and pheochromocytoma.

Usage in pregnancy

No adequate clinical studies have been performed to determine the safe use of doxapram in pregnancy. Until further clinical experience has been obtained, the physician must weigh the need against possible risks in using the drug in pregnant patients or in women of child-bearing potential.

Precautions—Recommended dosages of doxapram should be employed and maximum total dosages should not be exceeded. In patients with advanced pulmonary disease with hypoxemia, marked respiratory stimulation increases the work of breathing and may, thus, increase oxygen consumption and carbon dioxide production.

With excessive dosage, hyperventilation induced by doxapram may lead to respiratory alkalosis and hypocapnia with tetany and, theoretically, apnea.

An adequate airway is essential. In order to avoid side effects, it is advisable to use the minimum effective dosage. Monitoring of the blood pressure and deep tendon reflexes is recommended to prevent overdosage.

It is desirable that blood gases (P_{O_2} P_{CO_2} O_2 saturation) be monitored to assess the effectiveness of respiratory stimulation.

Intravenous barbiturates, oxygen and resuscitative equipment should be readily available to manage overdosage manifested by excessive central nervous system stimulation. Slow administration of the drug and careful observation of the patient during administration and for some time possibility of post-stimulation respiratory depression must be kept in mind. In patients who have been lightly curarized, doxapram may temporarily mask the residual effects of muscle relaxant drugs.

Doxapram should be administered cautiously to patients receiving sympathomimetic or monoamine oxidase inhibiting drugs, since a synergistic pressor effect may occur. It should likewise be used with care in post-operative patients with marked dyspnea due to obstructive pulmonary emphysema, acute or chronic asthma, profound metabolic disorders, severe to moderately severe hypertension, increased cerebrospinal fluid pressure, head injury and acute agitation.

Since doxapram may stimulate basal gastric secretion, it should be used with care in patients with peptic ulcer disease and in patients undergoing gastric surgery.

Vascular extravasation or use of a single injection site over an extended period should be avoided since either may lead to thrombophlebitis.

Hypocapnia accompanying forced ventilation is a potent stimulus to cerebral vasoconstriction; it may be postulated that some element of risk may exist from reduced cerebral blood flow following prolonged and intensive hyperventilation.

Since an increase in epinephrine release has been noted with doxapram, it is recommended that initiation of therapy with this respiratory stimulant be delayed for at least 10 minutes following the discontinuance of anesthetics known to sensitize the myocardium to catecholamines, such as halothane and cyclopropane.

As with other intravenous preparations, all precautions should be taken during administration of doxapram to insure that injection is made directly into a suitable vein; extravasation, and inadvertent intra-arterial injection should be avoided.

Adverse reactions—The following adverse reactions have been reported: *Central and Autonomic Nervous Systems.* Hyperactivity, feeling of warmth, sweating, muscle tremor, clonus, increased deep tendon reflexes, dizziness, muscle spasticity, pyrexia, confusion, paresthesia, pupillary dilatation, pilomotor erection, headache, bilateral babinski, fasciculation and carpopedal spasm. A grand mal seizure occurred 95 minutes after drug administration in a known epileptic patient who was on anticonvulsant medication.

Respiratory. Cough, dyspnea, laryngospasm, bronchospasm and hiccough.

Cardiovascular. Hypertension, sinus tachycardia, bradycardia, extrasystoles, lower T-waves, premature ventricular contractions, irregular heart rhythm, tightness in chest. Although a mild to moderate increase in blood pressure is not infrequent, such an increase may occasionally be of concern in hypertensive patients.

Gastrointestinal. Nausea and/or vomiting, salivation, stimulation of lower bowel, sour taste.

Genitourinary. Urinary retention, stimulation of urinary bladder with spontaneous voiding.

Miscellaneous. Pruritus, thrombophlebitis.

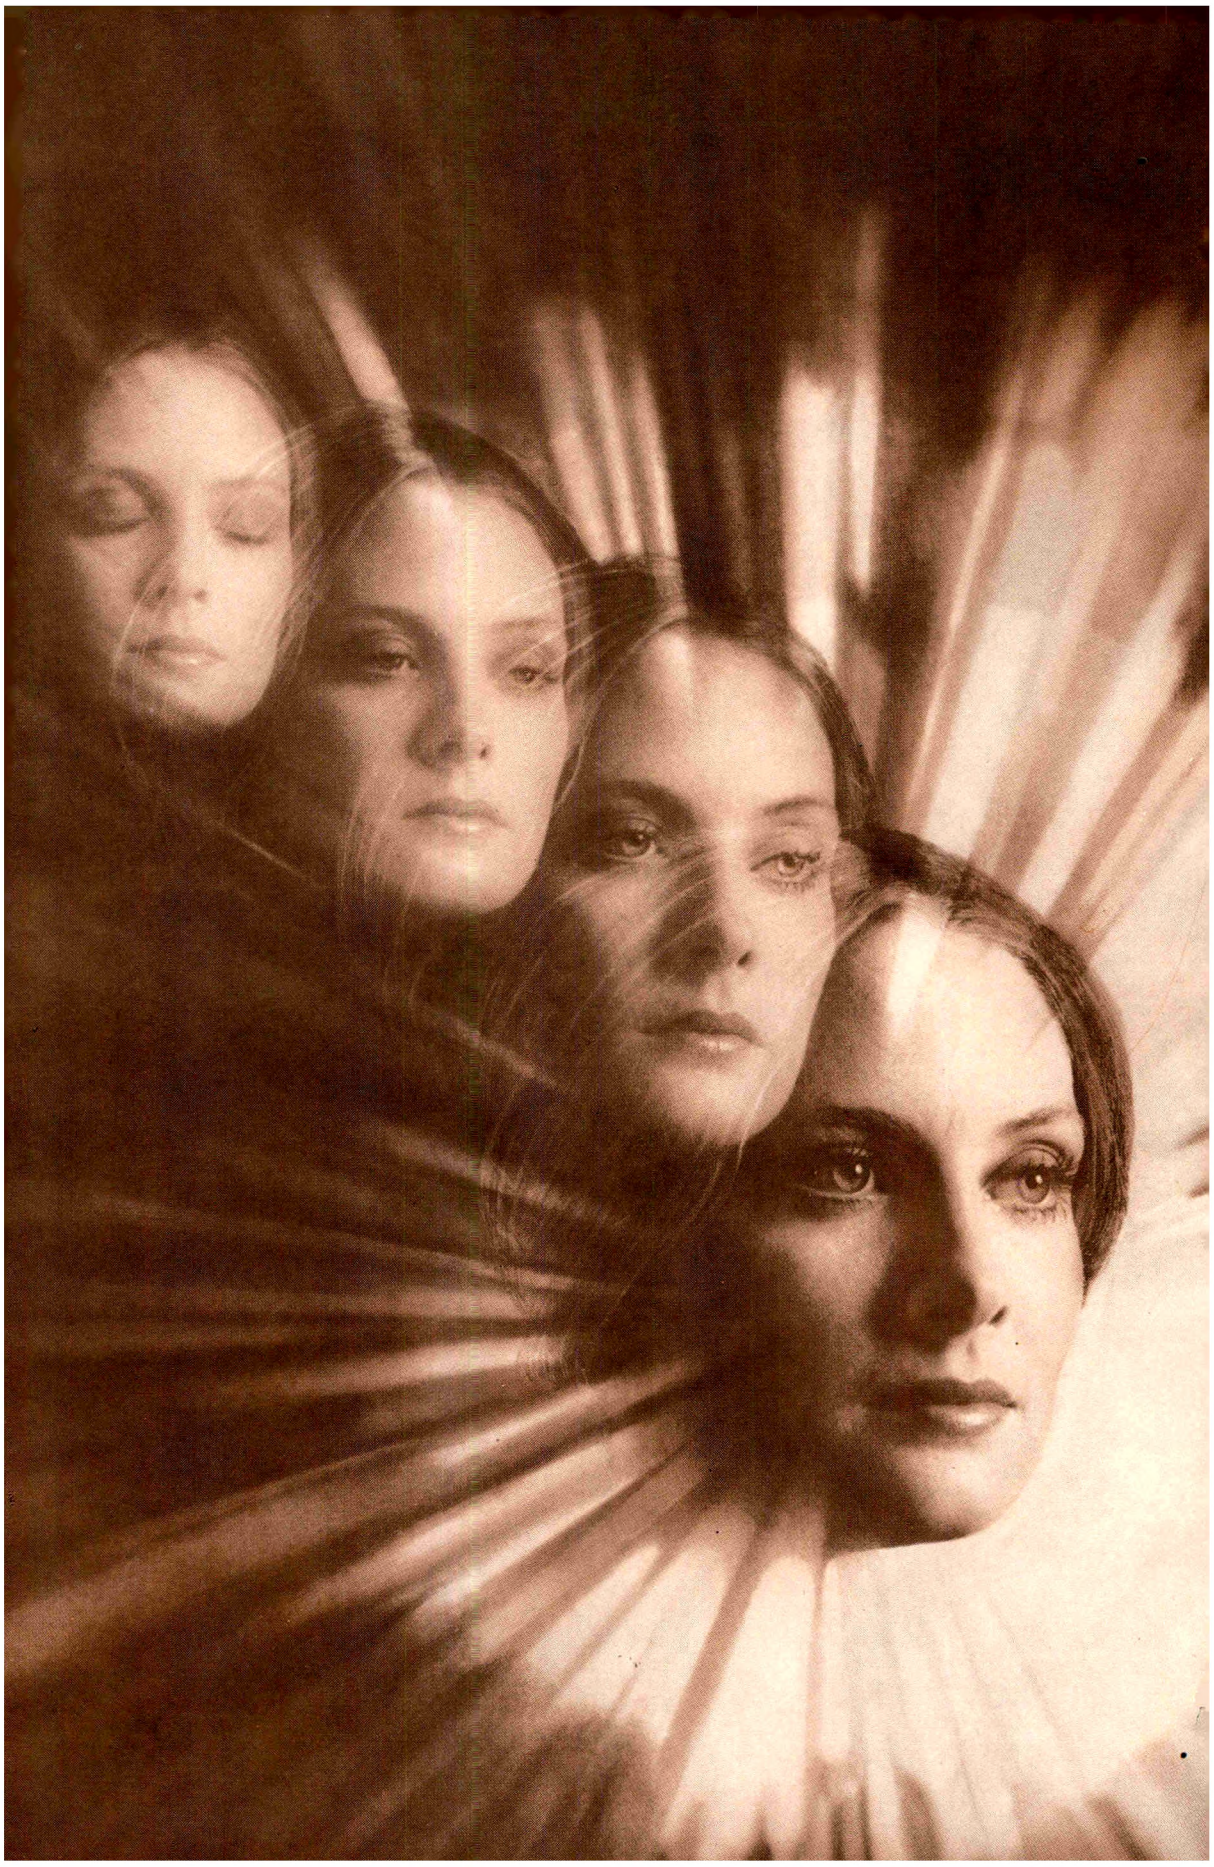
Laboratory Determinations. A decrease in hemoglobin, hematocrit, or red blood cell count has been observed in postoperative patients. In the presence of pre-existing leukopenia, a further decrease in WBC was observed following anesthesia and treatment with doxapram hydrochloride. Elevation of BUN and albuminuria have been observed.

In some of the cases cited above, the patients had received multiple drugs concomitantly, thus preventing an absolute judgment as to the role of doxapram in these reactions.

Dosage—For complete information concerning dosage and administration see package insert.

Supply—Dopram (doxapram hydrochloride) is available in 20 cc rubber stoppered vials containing 20 mg/cc, with chlorobutanol 0.5% as the preservative.

A. H. Robins Company
Richmond, Virginia 23220



A "quick recovery" anesthetic for short surgical procedures

Ethrane® (enflurane) fulfills your anesthetic requirements for short surgical procedures.

Fast Induction, Rapid Recovery. The low blood/gas partition coefficient of ETHRANE (1.91 at 37°C) assures rapid patient induction with minimal excitation. Its mild, pleasant odor is highly acceptable and ETHRANE does not stimulate increased salivation or affect bronchomotor tone.[1] Pharyngeal and laryngeal reflexes can be quickly and easily obtunded. Following anesthesia, because of its low blood solubility, ETHRANE is promptly eliminated at the lungs, permitting rapid emergence and recovery.[2]

Stable Cardiac Rhythm. Cardiac rhythm usually remains normal during ETHRANE anesthesia and is not altered even with elevations in arterial carbon dioxide.[3] Although nodal or atrial arrhythmias occasionally appear, ventricular extrasystoles are rare. Heart rate is sustained at preanesthetic levels. Bradycardia or tachycardia do not normally occur. Blood pressure tends to be reduced with induction, but this effect is reversed with surgical stimulation.[4]

Excellent Muscle Relaxation. At clinical concentrations, ETHRANE usually provides muscle relaxation sufficient for lower abdominal procedures. In addition, relaxation is often adequate for procedures of the upper abdomen. If greater relaxation is required, its potentiation of nondepolarizing relaxants reduces the dosage of such adjunctive neuromuscular blocking agents.[4]

Few Anesthetic Aftereffects. Following cessation of anesthesia with ETHRANE, recovery is rapid, uneventful, and complete. Postoperative return of adequate pulmonary ventilation is rapid.[1] Nausea, vomiting, and delirium are rare. Usually there is an early return of lucidity, desire for fluids, and generally a feeling of well-being.[1,5]

WARNING: Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. For additional warnings, contraindications, and precautions, see following page.

Films Available for Medical Education. As a service to the anesthesia profession, Ohio Medical Products has available, without charge, motion pictures for use in continuing medical education. Topics include such areas as "Management of Ambulatory Surgical Procedures" and "The Use of ETHRANE." To arrange for a personal or group showing, contact your OHIO Anesthetic Representative, or write to our Communications Department in Madison, Wisconsin.

Ethrane®
(enflurane)

Versatile in Concept–Versatile in Performance

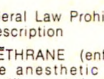
AIRCO®

See following page for full disclosure

Ethrane® (enflurane) Versatile in concept... Versatile in performance.

CAUTION: Federal Law Prohibits Dispensing without Prescription

Description: ETHRANE (enflurane) is a nonflammable anesthetic agent. It is 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether, and its structural formula is:



Some physical constants of the compound are:

Molecular weight	184.5
Boiling point 760 mm Hg.	56.5°C
Refractive index n_D^{20}	1.3026-1.3030
Specific gravity 25°/25°C	1.517
Vapor pressure in mm Hg.**	20°C 174.5 25°C 217.7 36°C 345.2

**Equation for calculation of enflurane vapor pressures:

$$\log_{10} P = A + \frac{B}{T}$$

A = 7.967
B = −1678.4
T = °C + 273.16 (Kelvin)

Partition coefficients @ 37°C	
Water-gas	0.82
Blood-gas	1.91
Oil-gas	98.5
Partition coefficients @ 25°C—rubber and plastic	
Conductive rubber	74.0
Butyl rubber	90.0
Polyvinylchloride	120.0
Polyethylene	≈2.0
Polyurethane	≈1.5
Polyolefin	≈1.2
Butyl acetate	≈3.0
Solubility of enflurane in H_2O at 22°C	0.275%
Solubility of H_2O in enflurane	0.13%
Purity by gas chromatography	>99.9%
Flammability in air	None
Flammability in oxygen (Entire concentration range to saturation at 71 and 113°F and 743 mm Hg. pressure.)	None
M.A.C. (Minimum alveolar concentration)	
Man with pure oxygen	1.68
Man with 70% nitrous oxide	0.56 (est.)

ETHRANE is a clear, colorless, stable liquid without added chemical stabilizers. ETHRANE has a mild, sweet odor. Storage of samples in indirect sunlight in clear, colorless glass for a five year period, as well as direct exposure for 30 hours to a 2 amp, 115 V., 60 cycle long wave U.V. light, produced no changes in composition detectable by gas chromatography. ETHRANE in one normal sodium methoxide-methanol solution, a strong base, for over six months consumed none of the alkali, indicative of strong base stability. ETHRANE does not decompose in contact with soda lime. ETHRANE does not attack aluminum, tin, brass, iron or copper.

Actions: ETHRANE (enflurane) is an inhalation anesthetic. Induction and recovery from anesthesia with ETHRANE are rapid. ETHRANE does not appear to stimulate excess salivation or tracheobronchial secretions, or affect bronchomotor tone. Pharyngeal and laryngeal reflexes are readily obtunded. The level of anesthesia changes rapidly with ETHRANE. ETHRANE reduces ventilation as depth of anesthesia increases. ETHRANE provokes a sigh response reminiscent of that seen with diethyl ether.

There is a decrease in blood pressure with induction of anesthesia, followed by a return to near normal with surgical stimulation. Progressive increases in depth of anesthesia produce corresponding increases in hypotension. Heart rate remains relatively constant without significant bradycardia. Electrocardiographic monitoring or recordings indicate that cardiac rhythm remains stable. Elevation of the carbon dioxide level in arterial blood does not alter cardiac rhythm. ETHRANE sensitizes the myocardial conduction system to epinephrine in dog and can produce serious arrhythmias. Comparable information in man is not available.

Muscle relaxation is adequate for intra-abdominal operation at normal levels of anesthesia. Should greater relaxation be necessary, minimal doses of muscle relaxants may be used. All commonly used muscle relaxants are compatible with ETHRANE. **The nondepolarizing muscle relaxants are markedly potentiated.** Neostigmine does not reverse the direct effect of ETHRANE.

Biotransformation of ETHRANE (enflurane) in man results in low levels of serum fluoride ions averaging 15 mM/L. These levels are well below the 50 mM/L seen to produce renal damage in normal subjects; however, it is possible that these levels could result in damage in patients with severely impaired renal function or those undergoing renal transplantation.

Indications: ETHRANE (enflurane) may be used for induction and maintenance of general anesthesia. Adequate data have not been developed to establish its application in obstetrical anesthesia.

Contraindications: Seizure disorders (see WARNINGS).

Known sensitivity to ETHRANE (enflurane) or other halogenated anesthetics.

Warnings: Increasing depth of anesthesia with ETHRANE (enflurane) produces a change in the electroencephalogram characterized by high voltage, fast frequency, progressing through spike-dome complexes alternating with periods of electrical silence to frank seizure activity. The latter may or may not be associated with motor movement. Motor activity, when encountered, generally consists of twitching or "jerks" of various muscle groups; it is self-limiting and can be terminated by lowering the anesthetic concentration. This electroencephalographic pattern associated with deep anesthesia is exacerbated by hyperventilation producing low arterial carbon dioxide tension. The pattern serves as a warning that depth of anesthesia is excessive. Cerebral blood flow and metabolism studies in normal volunteers during seizure patterns show no evidence of cerebral hypoxia, and recovery appears to be uncomplicated.

Since levels of anesthesia may be altered easily and rapidly, only calibrated vaporizers which measure output with reasonable accuracy should be used. Hypotension and respiratory exchange can serve as a guide to anesthesia depth. With deep levels of anesthesia, more marked hypotension and respiratory depression are encountered.

The action of nondepolarizing relaxants is augmented by ETHRANE. Less than the usual amounts of these drugs should be used. The time for recovery from the myoneural effect of these relaxants is greater in the presence of ETHRANE than for other commonly used anesthetics.

The safety of the use of epinephrine topically and subcutaneously has not been established in man.

Usage in Pregnancy: Safety in pregnancy has not been established. Reproduction studies have been performed in rats and rabbits, and there is no evidence of harm to the animal fetus. The relevance of these studies to the human is not known. Since there is no adequate experience in pregnant women who have received the drug, safety in pregnancy has not been established.

Precautions: Bromsulfalein (BSP) retention is mildly elevated postoperatively in some cases. There is some elevation of glucose and white blood count intraoperatively. Glucose elevation should be considered in diabetic patients. ETHRANE (enflurane) should be used with caution in patients who by virtue of medical or drug history could be considered more susceptible to cortical stimulation produced by this drug. As with other general anesthetics and some muscle relaxants, hyperpyrexia has been observed with the use of ETHRANE.

Adverse reactions: 1. Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. 2. Hypotension and respiratory depression have been reported. 3. Arrhythmias, shivering, nausea, and vomiting have been reported. 4. Elevation of the white blood count has been observed. It has not been determined whether this is related to ETHRANE or to surgical stress.

Dosage and administration: The concentration of ETHRANE (enflurane) being delivered during anesthesia from a vaporizer should be known. This may be accomplished by using:

a) vaporizers calibrated specifically for ETHRANE;
b) vaporizers from which delivered flows can easily and readily be calculated.

Maintenance concentration should not exceed 3%. Premedication should be selected according to the need of the individual patient, taking into account that secretions are weakly stimulated by ETHRANE and the heart rate remains constant. The use of anticholinergic drugs is a matter of choice.

Induction: Induction may be achieved using ETHRANE alone with oxygen or in combination with oxygen-nitrous oxide mixtures. Under these conditions some excitement may be encountered. If excitement is to be avoided, a hypnotic dose of a short-acting barbiturate should be used to induce unconsciousness, followed by the ETHRANE mixture. In general, inspired concentrations of 3.5-4.5% ETHRANE produce surgical anesthesia in 7-10 minutes.

Maintenance: Surgical levels of anesthesia may be attained with 1.5-3.0% concentration. If added relaxation is required, supplemental doses of muscle relaxants may be used. Ventilation to maintain the tension of carbon dioxide in arterial blood in the 35-45 mm range is preferred to hyper- or hypoventilation in order to minimize possible CNS excitation.

The level of blood pressure during maintenance is an inverse function of ETHRANE concentration in the absence of other complicating problems. Excessive decreases (unless related to hypovolemia) may be due to depth of anesthesia and in such instances should be corrected by lightening the level of anesthesia.

Overdosage: In the event of overdosage, or what may appear to be overdosage, the following action should be taken:

Stop drug administration; establish that the airway is clear and initiate assisted or controlled ventilation with pure oxygen as circumstances dictate.

Administration equipment: ETHRANE (enflurane) may be administered from a flow-through type vaporizer manufactured and specifically calibrated for ETHRANE. Vaporizers which deliver saturated vapor at reasonable flows but are not specifically calibrated for ETHRANE may be used.

ETHRANE contains no stabilizer. Nothing is present in the agent to alter calibration or affect the operation characteristics of the vaporizer.

Packaging: ETHRANE (enflurane) is packaged in 125 and 250 ml. amber bottles. No additives or stabilizers are present.

THE VULNERABLE EYE.

Lacri-Lube® protects the vulnerable eye of the anesthetized patient.

The under-protected eye is threatened during general anesthesia. Tape alone can leave your patient's eye vulnerable to dehydration and corneal erosion. And with medicated ointments, you unnecessarily risk allergic reactions and possible long-term sensitization.

Lacri-Lube meets your need for a safer, more sophisticated method of protecting and lubricating the eye. Either on its own or as an adjunct to taping. It's the first non-medicated, sterile ophthalmic ointment specifically designed to lubricate and protect the eye — and do nothing more.

In fact, ophthalmologists have established Lacri-Lube as their lubricant-protectant of choice whenever an eye is jeopardized by exposure or dehydration. And the rapid increase in its surgical use indicates that Lacri-Lube fulfills the same need among anesthesiologists.

Lacri-Lube is the ophthalmic for anesthesia.

When you consider the alternatives, you can't make a better choice.

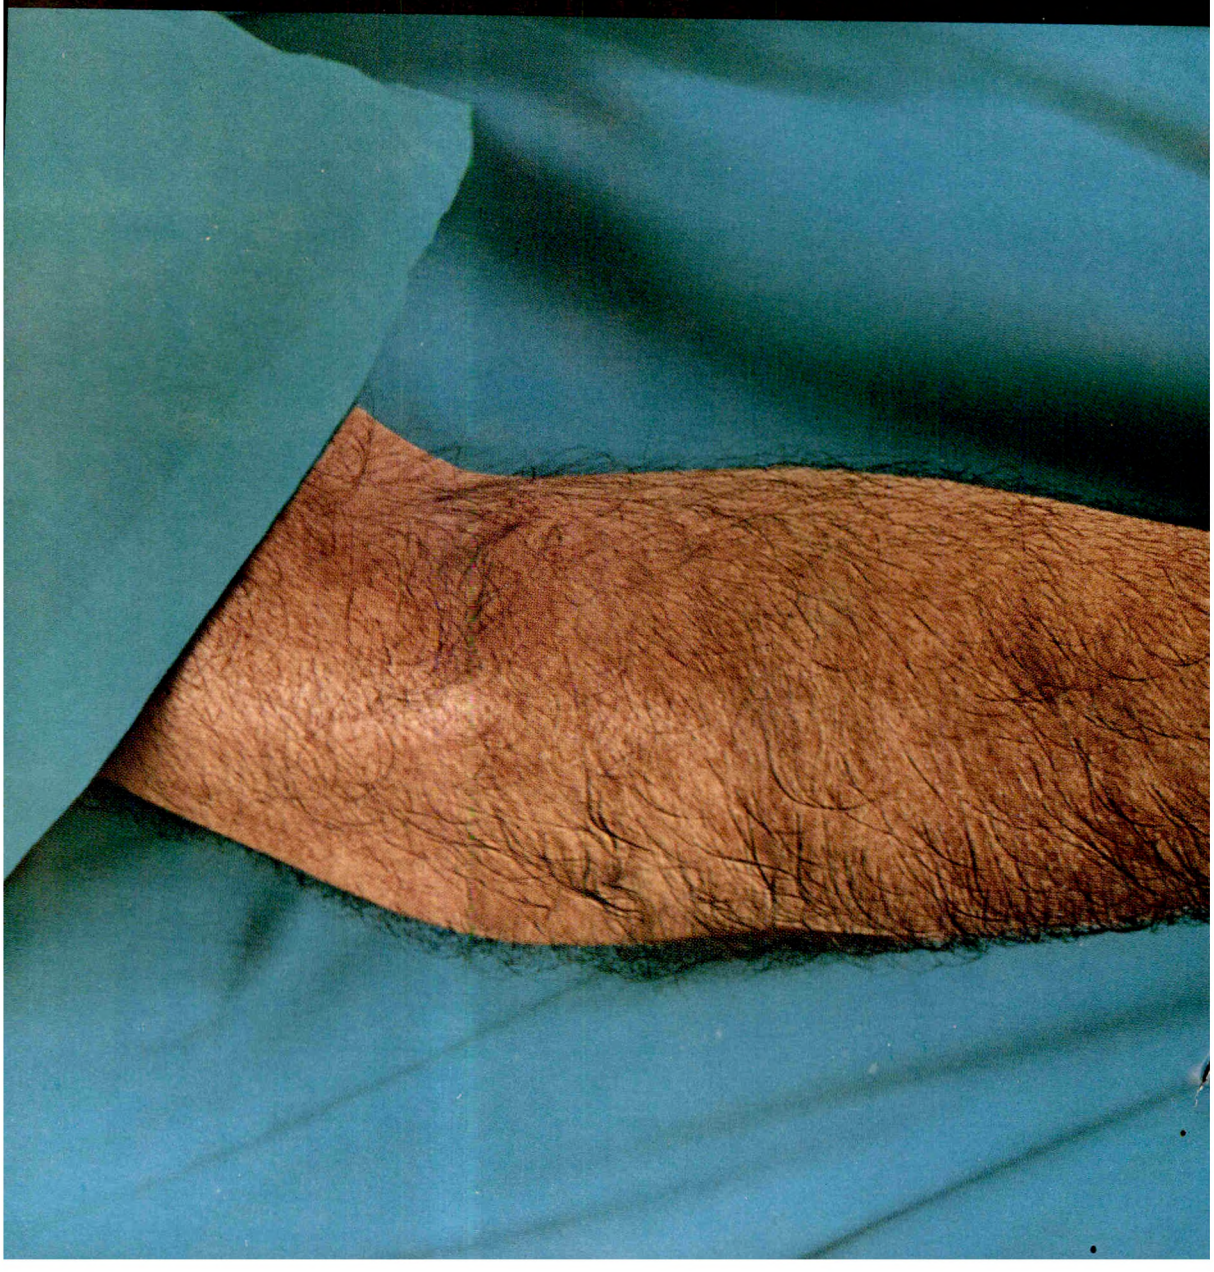
Take the Excessive Anxiety out of Anesthesia



Vistaril I.M. (hydroxyzine HCl) helps allay the anxiety that may complicate premedication, induction and recovery room emergence.

It has no significant depressant effects on respiratory or circulatory function and often reduces postoperative emesis.

Vital signs are seldom impaired. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.

And, because it may enhance the effect of injectable analgesics, requirements of narcotic and nonnarcotic analgesics, such as meperidine, morphine sulfate and pentazocine, may be reduced.

Vistaril I.M. is physically compatible with most commonly used analgesics, and can be mixed with them in the same syringe.

Alone, or as an adjunct for use with injectable analgesics, the maximum recommended dosage of Vistaril I.M. is 100 mg. While the analgesic dosage needed will usually be reduced, the actual dosage of Vistaril I.M. should be titrated against the individual patient's clinical response.

Vistaril® I.M.
(hydroxyzine HCl)
100 mg./2 ml., 50 mg./ml. and 25 mg./ml. Vials and Isojects®

Pfizer

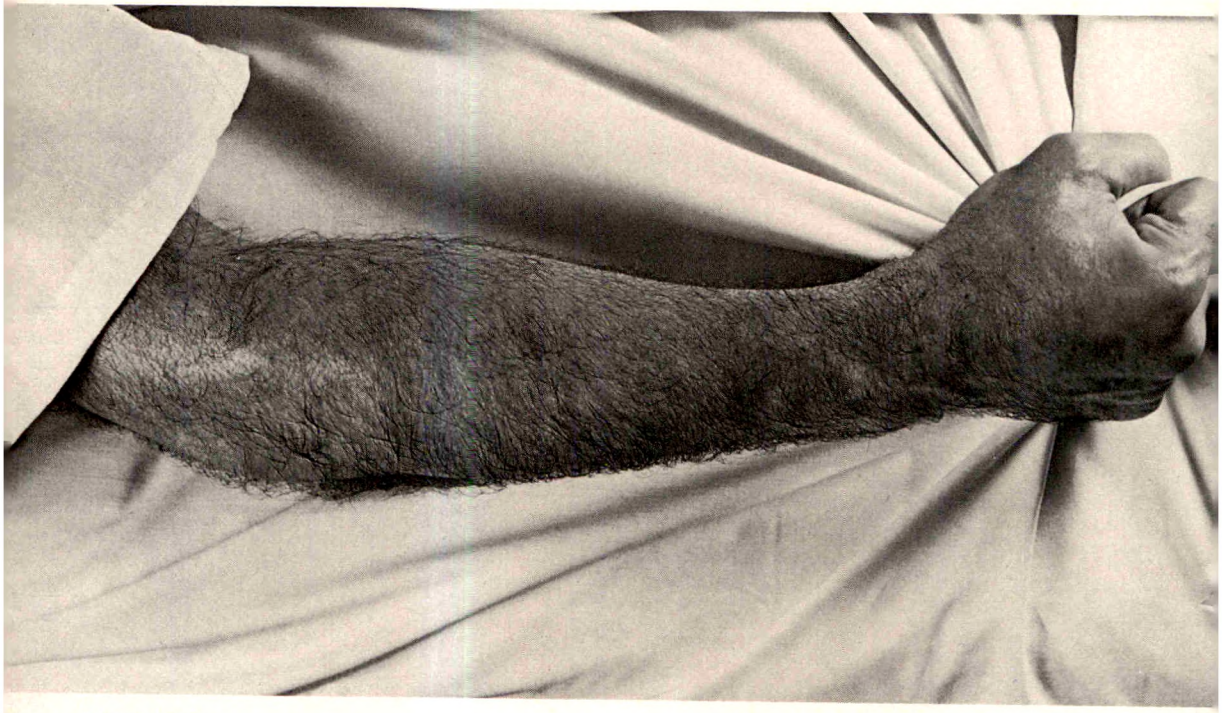
PFIZER INC.

Please see Brief Summary on following page for contraindications, precautions and adverse reactions.

Vistaril® I.M.
(hydroxyzine HCl)

100 mg./2 ml., 50 mg./ml. and 25 mg./ml.
Vials and Isojects®

Calm Before Anesthesia... In Recovery



Brief Summary
VISTARIL® (hydroxyzine hydrochloride) Intramuscular Solution
For Intramuscular Use Only

Contraindications: Hypersensitivity to hydroxyzine. The solution for intramuscular use *must not* be injected subcutaneously, intra-arterially, or intravenously.

Hydroxyzine, when administered to the pregnant mouse, rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Clinical data in human beings are inadequate. Until adequate data are available to establish safety in early pregnancy, hydroxyzine is contraindicated during this period.

Precautions: *Hydroxyzine may potentiate the action of central nervous system depressants such as narcotics and barbiturates.* In conjunctive use, dosage for these drugs should be decreased as much as 50%. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery. The usual precautions for intramuscular injection should be followed; soft-tissue reactions have rarely been reported when proper technique has been used. Hydroxyzine intramuscular solution should be injected well within the body of a relatively large muscle. In adults, the preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus), or the mid-lateral thigh. In children, preferably the mid-lateral muscle of the thigh. In infants and small children, the upper outer quadrant of the gluteal region should only be used when necessary, as in burn patients, in o to minimize the possibility of damage to the sciatic nerve. The deltoic area should be used only if well developed, such as in certain adults older children, and only with caution to avoid radial nerve injury. Injections should not be made in the lower and middle thirds of the upper arm. Aspiration is necessary to help avoid intravascular inject

Adverse Reactions: Drowsiness may occur; if so, it is usually transit and may disappear in a few days of continued therapy or upon dosag reduction. Dryness of the mouth may occur with higher doses. Involu tary motor activity, including rare instances of tremor and convulsion has been reported, usually with higher than recommended dosage.

Supply: Vistaril (hydroxyzine HCl) Intramuscular Solution: 25 mg./m 10 ml. vial; 50 mg./ml.—2 ml. and 10 ml. vial; Isoject®, 25 mg./ml. an 50 mg./ml., 1 ml. fill; 100 mg./2 ml., 2 ml. fill.
Military Depot: NSN 6505-00-052-1367 (50 mg./ml., 10 ml. vial)
VA Depot: NSN 6505-00-052-1367B (50 mg./ml., 10 ml. vial)

Innovar® injection

The two components of INNOVAR® injection, fentanyl and droperidol, have different pharmacologic actions. Before administering INNOVAR injection, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action.

DESCRIPTION

Each cc. contains (in a 1:50 ratio):

Fentanyl ..... 0.05 mg.
as the citrate

Warning: May be habit forming

Droperidol ..... 2.5 mg.
Lactic acid for adjustment of pH to 3.5± 0.3

FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY

Protect from Light

ACTIONS INNOVAR injection is a combination drug containing a narcotic analgesic, fentanyl, and a neuroleptic (major tranquilizer), droperidol. The combined effect, sometimes referred to as neuroleptanalgesia, is characterized by general quiescence, reduced motor activity, and profound analgesia; complete loss of consciousness usually does not occur from use of INNOVAR injection alone. The incidence of early postoperative pain and emesis may be reduced.

A. Fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. Fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. Fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays, and skin wheal testing in man, as well as *in vivo* testing in dogs indicate that histamine release rarely occurs with fentanyl.

Fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours. Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics, it may be considerably longer than the analgesic effect.

B. Droperidol produces marked tranquilization and sedation. It also produces an antiemetic effect as evidenced by the antagonism of apomorphine in dogs. It potentiates other CNS depressants. It also produces mild alpha adrenergic blockade, peripheral vascular dilatation and reduction of the pressor effect of epinephrine. Droperidol can produce hypotension and decreased peripheral vascular resistance. It may decrease pulmonary arterial pressure (particularly if it is abnormally high). It may reduce the incidence of epinephrine-induced arrhythmias but it does not prevent other cardiac arrhythmias. The onset of action is from three to ten minutes following intravenous or intramuscular administration. The full effect, however, may not be apparent for 30 minutes. The duration of the sedative and tranquilizing effects generally is two to four hours. Alteration of consciousness may persist as long as 12 hours. This is in contrast to the much shorter duration of action of fentanyl.

INDICATIONS INNOVAR injection is indicated to produce tranquilization and analgesia for surgical and diagnostic procedures. It may be used as an anesthetic premedication, for the induction of anesthesia, and as an adjunct in the maintenance of general and regional anesthesia. If the supplementation of analgesia is necessary, SUBLIMAZE® (fentanyl) injection alone rather than the combination drug INNOVAR injection should usually be used.

CONTRAINDICATIONS INNOVAR injection should not be used in patients who are hypersensitive to either component.

WARNINGS PATIENTS WHO HAVE RECEIVED *INNOVAR* INJECTION SHOULD BE UNDER APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

The respiratory depressant effect of narcotics persists longer than their measured analgesic effect. When used with INNOVAR injection, the total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, be used initially in reduced doses, as low as 1/4 to 1/3 those usually recommended.

INNOVAR injection may cause muscle rigidity, particularly involving the muscles of respiration. This effect is due to the fentanyl component and is related to the speed of injection. Its incidence can be reduced by the use of slow intravenous injection. Once the effect occurs it is managed by the use of assisted or controlled respiration and by a neuromuscular blocking drug, if necessary.

FLUIDS AND OTHER COUNTERMEASURES TO MANAGE HYPOTENSION SHOULD ALSO BE AVAILABLE.

Drug Dependence: *Fentanyl, the narcotic analgesic component, can produce drug dependence of the morphine type and therefore has the potential for being abused.*

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl, in this regard, has not been established, the use of INNOVAR injection or SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: INNOVAR injection should be used with caution in patients who may be particularly susceptible to respiratory depression such as comatose patients who may have a head injury or brain tumor. In addition, these drugs may obscure the clinical course of patients with head injury.

Usage in Children: The safety of INNOVAR injection in children two years of age or younger has not been established.

Usage in Pregnancy: The safe use of INNOVAR injection has not been established with respect to possible adverse effects upon fetal development.

Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

PRECAUTIONS *The initial dose of INNOVAR injection should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves, and can cause peripheral vasodilatation and hypotension because of sympathetic blockade. Through other mechanisms (see Actions) fentanyl and droperidol also depress respiration and blood pressure. Therefore, when INNOVAR injection is used to supplement these forms of anesthesia, the anesthetist must be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for this form of anesthesia.

The droperidol component of INNOVAR injection may decrease pulmonary arterial pressure. This fact should be considered by those who conduct diagnostic or surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Vital signs should be monitored routinely.

INNOVAR injection, and SUBLIMAZE fentanyl, should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised ventilation. In such patients narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia this can be managed by assisted or controlled respiration. Postoperatively respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone); consult individual prescribing information before using.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) have additive or potentiating effects with INNOVAR injection. When patients have received such drugs, the dose of INNOVAR injection required will be less than usual. Likewise, following the administration of INNOVAR injection the dose of other CNS depressant drugs should be reduced.

INNOVAR injection should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

If hypotension occurs, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. It should be noted that in spinal and peridural anesthesia, tilting the patient into a head down position may result in a higher level of anesthesia than is desirable, as well as impair venous return to the heart. Care should be exercised in the moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus these other countermeasures do not correct the hypotension, then the administration of pressor agents other than epinephrine should be considered. Epinephrine may paradoxically decrease the blood pressure in patients treated with INNOVAR injection due to the alpha-adrenergic blocking action of droperidol.

The fentanyl component may produce bradycardia, which may be treated with atropine; however, INNOVAR injection should be used with caution in patients with cardiac bradyarrhythmias.

When the EEG is used for postoperative monitoring, it may be found that the EEG pattern returns to normal slowly.

ADVERSE REACTIONS The most common serious adverse reactions reported to occur with INNOVAR injection are respiratory depression, apnea, muscular rigidity, and hypotension; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with anti-parkinson agents.

Other adverse reactions that have been reported are dizziness, chills and/or shivering, twitching, blurred vision, hyperactivity on induction, laryngospasm, transient hypertension, nausea and emesis, diaphoresis, emergence delirium, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression).

Postoperative drowsiness is also frequently reported.

OVERDOSAGE ***Manifestations:*** The manifestations of INNOVAR injection overdosage are an extension of its pharmacologic actions.

Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered. A specific narcotic antagonist such as nalorphine, levallorphan or naloxone should be available for use as indicated to manage respiratory depression caused by the narcotic component fentanyl. This does not preclude the use of more immediate countermeasures. Consult the package inserts for the individual narcotic antagonists for details about use.

HOW SUPPLIED INNOVAR® injection is supplied in 2 cc. (**NDC** 0045-0280-20) and 5 cc. (**NDC** 0045-0280-50) ampuls, in packages of 10.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

ANTILIRIUM
(Physostigmine Salicylate)

REVERSES MOST POST-OPERATIVE DELIRIUM AND PROLONGED SOMNOLENCE

Before prescribing, please consult complete product information, a summary of which follows:

ACTION: ANTILIRIUM (physostigmine salicylate) is a salicylic acid derivative of an alkaloid extracted from seeds of Physostigma Venenosum (calabar bean). The action of the parasympathetic nerves is intermediated by the formation of acetylcholine at the peripheral end of these nerves. Physostigmine inhibits the destructive action of cholinesterase and thereby prolongs and exaggerates the effect of the acetylcholine.

Physostigmine contains a tertiary amine and easily crosses the blood brain barrier, while neostigmine contains a quaternary amine and is not capable of crossing the structure. This may explain why neostigmine does not cause reversal of anticholinergic-induced delirium while physostigmine does.

INDICATIONS: TO REVERSE THE TOXIC EFFECTS UPON THE CENTRAL NERVOUS SYSTEM CAUSED BY DRUGS IN CLINICAL OR TOXIC DOSAGES CAPABLE OF PRODUCING ANTICHOLINERGIC POISONING.

SEVERE ANTICHOLINERGIC POISONING MAY PRODUCE:
COMA, MEDULLARY PARALYSIS AND DEATH.

CENTRAL TOXIC EFFECTS MAY INCLUDE: HALLUCINATIONS, DELIRIUM, DISORIENTATION, ANXIETY AND HYPERACTIVITY.

Dramatic reversal within minutes of coma, hallucinations, and other signs can be expected if the diagnosis is correct and the patient has not suffered anoxia or other insult. Therapeutic doses may be necessary at intervals as life-threatening signs recur. Physostigmine is destroyed in the body in 60 to 120 minutes.

CONTRAINDICATIONS: Physostigmine should not be used in the presence of asthma, gangrene, diabetes, cardiovascular disease, mechanical obstruction of the intestines or urogenital tract or any vagotonic state, and in patients receiving choline esters or depolarizing neuromuscular blocking agents.

WARNING: If excessive symptoms of salivation, emesis, urination and defecation occur, the use of ANTILIRIUM should be terminated. If excessive sweating or nausea occur, the dosage should be reduced.

Intravenous administration should be at a slow, controlled rate, no more than 1 mg. per minute (see dosage). Rapid administration can cause bradycardia, hypersalivation leading to respiratory difficulties and possibly convulsions.

An overdosage of ANTILIRIUM can cause a cholinergic crisis.

PRECAUTIONS: Because of the possibility of hypersensitivity in an occasional patient, atropine sulfate injection should always be at hand since it is an antagonist and antidote for physostigmine.

ADMINISTRATION AND DOSAGE: The usual adult dose of ANTILIRIUM is 0.5 to 2.0 mg. intramuscularly or intravenously. Intravenous administration should be at a slow, controlled rate of no more than 1 mg. per minute. It may be necessary to repeat dosages of 1 mg. to 4 mg. at intervals as life threatening signs such as arrhythmias, convulsions and deep coma recur.

IN ALL CASES OF POISONING, THE USUAL SUPPORTIVE MEASURES SHOULD BE UNDERTAKEN.

SUPPLIED: 2 ml. ampules containing:
PHYSOSTIGMINE SALICYLATE 1 mg. per ml.
Packed 12 ampules per box.

NDC 0456-1037-12

CAUTION: Federal law prohibits dispensing without prescription.

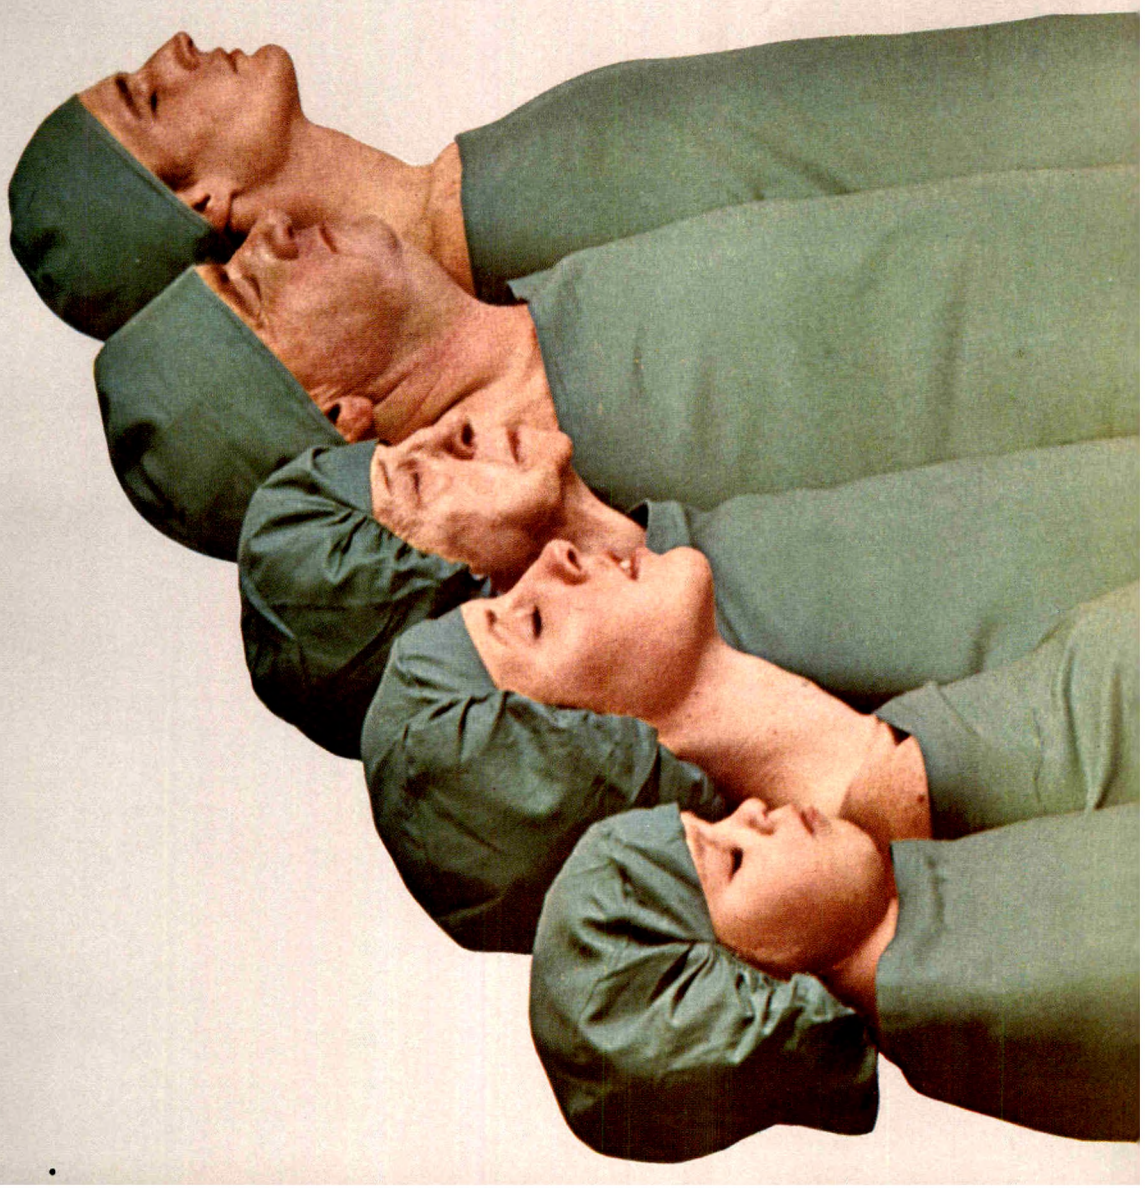
Clinically proven
nondepolarizing muscle relaxant

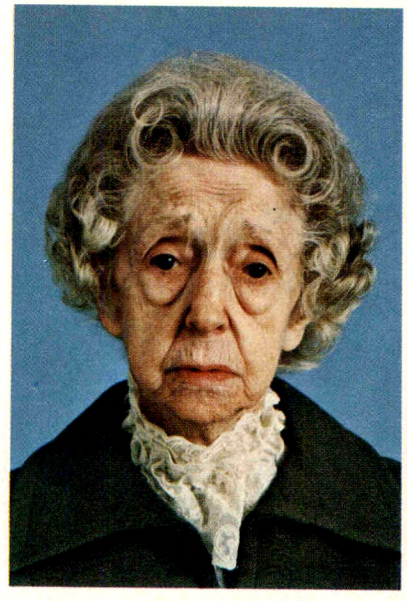
PAVULON®
pancuronium bromide

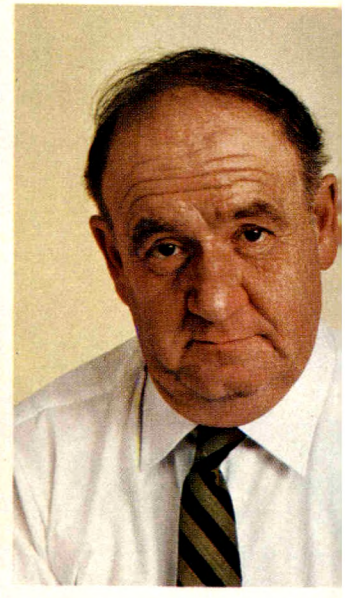
for many patients
for many reasons



An unusually fast-acting nondepolarizing blocking agent [1-5]

PAVULON®
pancuronium bromide





for many patients for many reasons

in pediatric surgery[6-12]

Pavulon® has been used with satisfactory results in pediatric patients undergoing elective surgery[11], abdominal surgery[7] and cardiovascular surgery[8]. Dose response studies indicate that, except for neonates, dosage is the same as for adults. In neonates, a test dose of 0.02 mg/kg is recommended to determine responsiveness.

in geriatric surgery[13]

Pavulon® can be considered a preferred relaxant for major surgical procedures in the aged patient because of the relative absence of significant side effects.

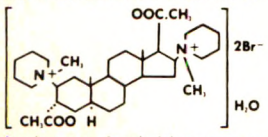
in the high risk patient[2-5, 14-18]

Pavulon® is often preferre for poor risk patients[5,14] especially those with asthn or chronic bronchitis[2,14,16,] cardiovascular disease[4,5,] [18] and patients undergoir abdominal, thoracic or oth major surgery[2,5], includir open heart surgery[15]. Ca tion should be exercise however, in the presence renal disease since a majc portion of the administere drug is excreted unchange in the urine.

PAVULON® (pancuronium bromide)

• THIS DRUG SHOULD ONLY BE ADMINISTERED BY ADEQUATELY TRAINED INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS, AND HAZARDS.

DESCRIPTION: Pavulon (pancuronium bromide) is the aminosteroid 2 beta, 16 beta-dipiperidine-5 alpha-androstane-3 alpha, 17 beta-diol diacetate dimethobromide. It has the following structural formula:



ACTIONS: Pavulon is a non-depolarizing neuromuscular blocking agent possessing all of the characteristic pharmacological actions of this class of drugs (curariform) on the myoneural junction.

Pavulon is approximately 5 times as potent as d-tubocurarine chloride.

The onset and duration of action of Pavulon is dose dependent. With the administration of 0.04 mg. per kg. the onset of action, as measured by a peripheral nerve stimulator, is usually within 45 seconds, and its peak effect is usually within 4½ minutes; recovery to 90% of control twitch height usually takes place in less than one hour. Larger doses, more suitable for endotracheal intubation, such as 0.08 mg. per kg. of Pavulon have an onset of action of about 30 seconds, and a peak effect within 3 minutes. Supplemental incremental doses of Pavulon, following the initial dose, slightly increase the magnitude of blockade, and significantly increase the duration of the blockade.

Pavulon has little effect upon the circulatory system. The most frequently reported observation is a slight rise in pulse rate.

Human histamine assays, and clinical observations, as well as in *vivo* guinea pig testing, and in *vitro* mast cell testing, indicate that histamine release rarely, if ever, occurs.

Pavulon is antagonized by acetylcholine, anticholinesterases, and potassium ion. Its action is increased by inhalational anesthetics such as halothane, diethyl ether, and methoxyflurane, as well as quinine, magnesium salts, hypokalemia, some carcinomas, and certain antibiotics such as neomycin, streptomycin, kanamycin, and bacitracin. The action of Pavulon may be altered by dehydration, electrolyte imbalance, acid-base imbalance, renal disease, and concomitant administration of other neuromuscular agents.

Pavulon has no known effect on consciousness, the pain threshold, or cerebration.

INDICATIONS: Pavulon is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may also be employed to facilitate the management of patients undergoing mechanical ventilation.

CONTRAINDICATIONS: Pavulon is contraindicated in patients known to be hypersensitive to the drug or to the bromide ion.

WARNINGS: PAVULON SHOULD BE ADMINISTERED IN CAREFULLY ADJUSTED DOSAGE BY OR UNDER THE SUPERVISION OF EXPERIENCED CLINICIANS, WHO ARE FAMILIAR WITH ITS ACTIONS AND THE POSSIBLE COMPLICATIONS THAT MIGHT OCCUR FOLLOWING ITS USE. THE DRUG SHOULD NOT BE ADMINISTERED UNLESS FACILITIES FOR INTUBATION, ARTIFICIAL RESPIRATION, OXYGEN THERAPY, AND REVERSAL AGENTS ARE IMMEDIATELY AVAILABLE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR CONTROL RESPIRATION.

In patients who are known to have myasthenia gravis small doses of Pavulon may have profound effects. A peripheral nerve stimulator is especially valuable in assessing the effects of Pavulon in such patients.

USAGE IN PREGNANCY: The safe use of pancuronium bromide has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards. There are insufficient data to support safe use of Pavulon in obstetrics, so such use is not recommended.

PRECAUTIONS: Although Pavulon has been used successfully in many patients with pre-existing pulmonary, hepatic, or renal disease, caution should be exercised in these situations. This is particularly true of renal disease since a major portion of administered Pavulon is excreted unchanged in the urine.

ADVERSE REACTIONS: Neuromuscular: The most frequently noted adverse reactions consist primarily of an extension of the drug's pharmacological actions beyond the time period needed for surgery and anesthesia. This may vary from skeletal muscle weakness to profound and prolonged skeletal muscle relaxation resulting in respiratory insufficiency or apnea. Inadequate reversal of the neuromuscular blockade by anticholinesterase agents has also been observed with Pavulon (pancuronium bromide) as with all curariform drugs. These adverse reactions are managed by manual or mechanical ventilation until recovery is judged adequate.

Cardiovascular: A slight increase in pulse rate is frequently noted.

Gastrointestinal: Salivation is sometimes noted during very light anesthesia, especially if no anticholinergic premedication is used.

Skin: An occasional transient rash is noted accompanying the use of Pavulon.

Respiratory: One case of wheezing, responding to deepening of the inhalational anesthetic, has been reported.

DRUG INTERACTION: The intensity of blockade and duration of action of Pavulon is increased in patients receiving potent volatile inhalational anesthetics such as halothane, diethyl ether, enflurane, and methoxyflurane. No increase in intensity of blockade or duration of action of Pavulon is noted from the use of thiobarbiturates, narcotic analgesics, nitrous oxide, or droperidol.

Prior administration of succinylcholine, such as that used for endotracheal intubation, enhances the relaxant effect of Pavulon and the duration of action. If succinylcholine is used before Pavulon, the administration of Pavulon should be delayed until the succinylcholine shows signs of wearing off.

DOSAGE AND ADMINISTRATION: Pavulon should be administered only by or under the supervision of experienced clinicians. DOSAGE MUST BE INDIVIDUALIZED IN EACH CASE. The dosage information which follows has been derived from dose-response studies based on body weight and is intended to serve as a guide only. Since potent inhalational agents or prior administration of succinylcholine enhance the intensity of blockade and duration of Pavulon (see DRUG INTERACTION), these factors should be taken into consideration in selection of initial and incremental dosage.

In adults the initial intravenous dosage range is 0.04 to 0.1 mg. per kg. Later incremental doses starting at 0.01 mg. per kg. may be used. These increments slightly increase the magnitude of the blockade, and significantly increase the duration of blockade, because a significant number of myoneural junctions are still blocked when there is clinical need for more drug.

If Pavulon is used to provide skeletal muscle relaxation for endotracheal intubation, doses of 0.06 to 0.1 mg. per kg. are recommended. Conditions satisfactory for intubation are usually present within 2 to 3 minutes. The ability of the anesthetist to intubate with Pavulon (pancuronium bromide) improves with experience.

Dosage in Children; Dose-response studies in children indicate that, with the exception of neonates, dosage requirements are the same as for adults. Neonates are especially sensitive to nondepolarizing neuromuscular blocking agents, such as Pavulon, during the first month of life. It is recommended that a test dose of 0.02 mg. per kg. be given first in this group to measure responsiveness.

MANAGEMENT OF PROLONGED NEUROMUSCULAR BLOCKADE: Residual neuromuscular blockade beyond the time period needed for surgery and anesthesia may occur with Pavulon as with other neuromuscular blockers. This may be manifested by skeletal muscle weakness, decreased respiratory reserve, low tidal volume or apnea. A peripheral nerve stimulator may be used to assess the degree of residual neuromuscular blockade. Under such circumstances the primary treatment is manual or mechanical ventilation and maintenance of a patent airway until complete recovery of normal respiration is assured. Regonol® (pyridostigmine bromide) or neostigmine, in conjunction with atropine, will usually antagonize the skeletal muscle relaxant action of Pavulon. These should be accompanied by or preceded by injection of atropine sulfate to minimize the incidence of cholinergic side effects, notably excessive secretions and bradycardia. Satisfactory reversal can be judged by adequacy of skeletal muscle tone, and by adequacy of respiration. A peripheral nerve stimulator may also be used to monitor restoration of twitch height. Failure of prompt reversal (within 30 minutes) may occur in the presence of extreme debilitation, carcinomatosis, and with concomitant use of certain broad spectrum antibiotics, or anesthetic agents and adjuncts which enhance neuromuscular blockade or cause respiratory depression of their own. Under such circumstances the management is the same as that of prolonged neuromuscular blockade; ventilation must be supported by artificial means until the patient has resumed control of his respiration. Prior to the use of reversal agents, reference to the specific package insert of the reversal agents should be made.

CAUTION: Federal law prohibits dispensing without prescription.

HOW SUPPLIED:

2 ml. ampuls—2 mg./ml.—box of 25
5 ml. ampuls—2 mg./ml.—box of 25
10 ml. multiple dose vials—1 mg./ml.—box of 25

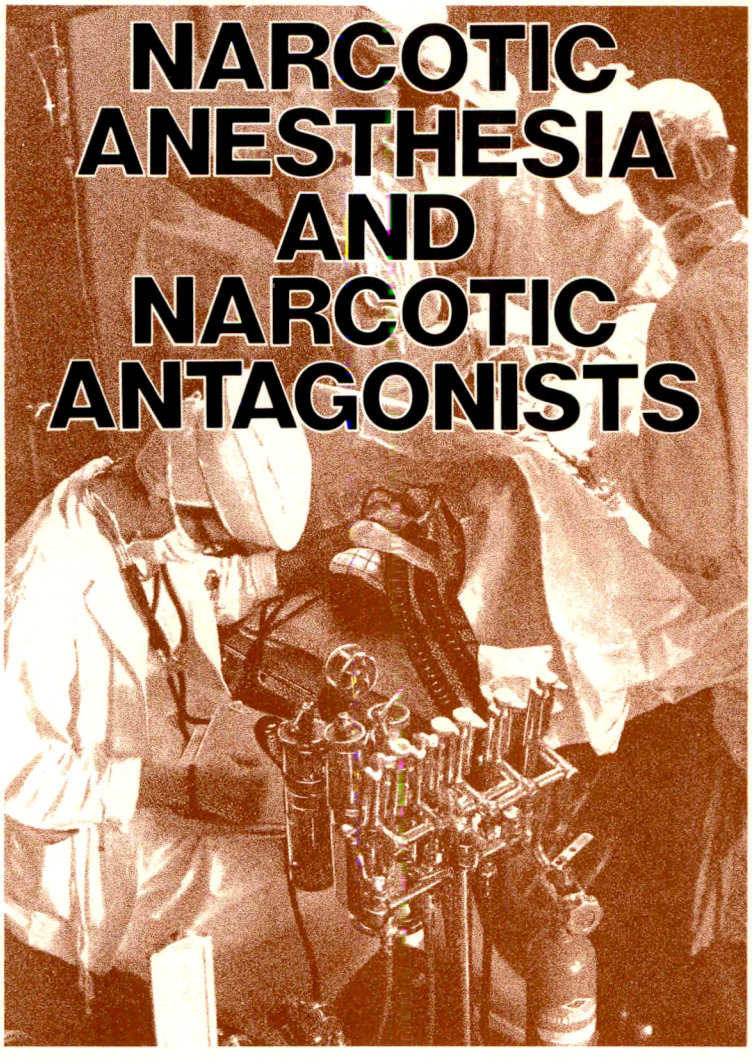
Organon

Organon Inc.
West Orange, N. J. 07052



NARCOTIC ANESTHESIA

- Despite many advantages, the use of opioids to supplement nitrous oxide anesthesia may be associated with significant postoperative depression.

NARCAN® (naloxone HCl)

- Narcan® in sufficient doses will antagonize opioid effects, including all degrees of respiratory depression and analgesia.
- The degree of narcotic antagonism exhibited by NARCAN® is dose dependent.

A recent study of surgical patients receiving narcotic-nitrous oxide anesthesia was undertaken to determine whether careful titration of naloxone would reverse post-operative narcotic depression and maintain a subjective level of analgesia.[1]

THE OBJECTIVES:

- Restore consciousness
- Reverse narcotic-induced respiratory depression as evidenced by $PaCO_2$
- Maintain *subjective* analgesia

THE METHOD:

- 12 unpremedicated patients received INNOVAR® (fentanyl/droperidol) 5-10 ml I.V. followed by thiopental for induction. Anesthesia was maintained with N_2O-O_2. Increments of 0.1 mg *fentanyl* were given I.V. every 10 minutes during surgery.

Following the procedure, naloxone (0.1 mg/ml) was given in 0.1 mg I.V. increments at 1 minute intervals until the patient was awake, lucid and had adequate tidal and minute volumes. Additional naloxone

1. Heisterkamp DV, Cohen PJ: *Anesth Analg* (Cleve) *53*:12-18, Jan-Feb 1974.

NARCAN® is an Endo registered U.S. trademark; U.S. Pat. 3,254,088.

was given I.V. as needed in the first 6 patients; a second group of 6 patients received supplemental naloxone I.M. 30 minutes after the initial I.V. dose.

- 11 patients received 10 mg *morphine* I.M., as well as secobarbital and atropine, 1½ hours preoperatively. Anesthesia was induced by 30 mg morphine given slowly I.V. followed by thiopental and was maintained by N_2O-O_2. Additional morphine was given in divided increments to total 1 mg/kg in the first hour. Further morphine was given as needed. For initial narcotic reversal, naloxone was given as above except at 2 minute intervals. Supplemental naloxone was given I.M. 30 minutes later.

THE RESULTS (fentanyl group):

- When fentanyl was used as the sole narcotic supplement during anesthesia, an I.M. dose of naloxone equal to half the I.V. reversal dose and given ½ hour later provided adequate narcotic reversal.

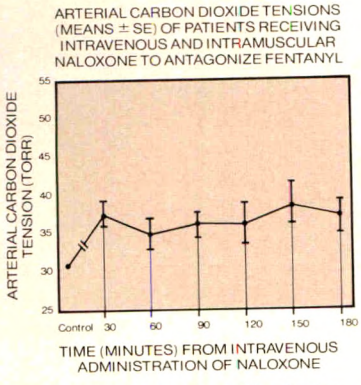


Fig. 1. Control and postoperative $PaCO_2$ in 6 patients receiving I.V. and I.M. naloxone following fentanyl.

THE RESULTS (morphine group):

- "After other narcotics, such as morphine, an I.M. dose of naloxone equal to the I.V. dose appears appropriate."

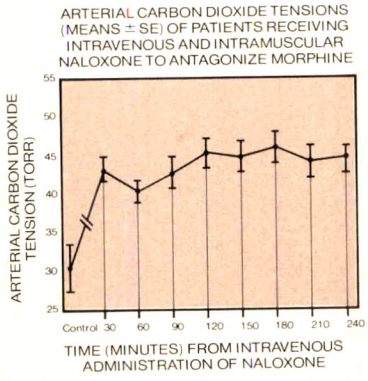

Fig. 2. Control and postoperative $PaCO_2$ in 11 patients receiving I.V. and I.M. naloxone following morphine.

THE CONCLUSIONS:

- "Naloxone provides fast, potent, and reliable antagonism to narcotic-induced respiratory depression."
- "By careful titration, this antagonism can be achieved while acceptable analgesia is maintained."
- "Both morphine and fentanyl groups had adequate analgesia, with only 2 patients [of total 21] requiring pain medication in the recovery room."

- **reverses all degrees of narcotic-induced respiratory depression**
- **does not cause narcotic-like effects**
- **does not augment non-narcotic depression**
- **acts rapidly—generally within 2 minutes following I.V. use and slightly less rapidly when given I.M.**
- **does not lead to tolerance**
- **does not produce psychotomimetic effects or pupillary constriction**
- **can be repeated if initial dose doesn't produce desired degree of narcotic reversal and improvement in respiratory function**
- **following satisfactory response patient should be observed closely and given repeat doses, if necessary, since the duration of action of some narcotics may exceed that of NARCAN®**

DUPONT

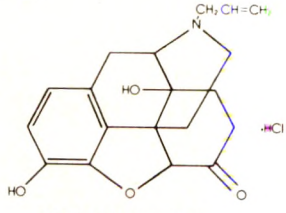
•restored consciousness
•reversed narcotic-induced respiratory depression
•maintained subjective analgesia

NARCAN®
(n lo -n- HCl)

can reverse narcotic-induced respiratory depression while maintaining subjective analgesia

NARCAN® (naloxone HCl)

DESCRIPTION NARCAN® (naloxone hydrochloride), a narcotic antagonist, is a synthetic congener of oxymorphone. In structure it differs from oxymorphone in that the methyl group on the nitrogen atom is replaced by an allyl group.



NALOXONE HYDROCHLORIDE
(N-allyl-nor-oxymorphone HCl)

Naloxone hydrochloride occurs as slightly off-white crystals, and is soluble in water, slightly soluble in alcohol and practically insoluble in ether.

NARCAN® (naloxone hydrochloride) Injection is available in two concentrations, 0.02 mg and 0.4 mg of naloxone hydrochloride per ml. Each ml of either strength contains 8.5 mg of sodium chloride; and 2.0 mg of methylparaben and propylparaben as preservatives in a ratio of 9 to 1. pH is adjusted with hydrochloric acid.

ACTIONS NARCAN® (naloxone hydrochloride) is an essentially pure narcotic antagonist, i.e., it does not possess the "agonistic" or morphine-like properties characteristic of other narcotic antagonists; NARCAN® (naloxone hydrochloride) does not produce respiratory depression, psychotomimetic effects or pupillary constriction. In the absence of narcotics or agonistic effects of other narcotic antagonists it exhibits essentially no pharmacologic activity.

In the presence of physical dependence on narcotics NARCAN® (naloxone hydrochloride) will produce withdrawal symptoms; it has not been shown to produce tolerance nor to cause physical or psychological dependence.

When NARCAN® (naloxone hydrochloride) is administered intravenously the onset of action is generally apparent within two minutes; the onset of action is only slightly less rapid when it is administered subcutaneously or intramuscularly. The duration of action is dependent upon the dose and route of administration of NARCAN® (naloxone hydrochloride). Intramuscular administration produces a more prolonged effect than intravenous administration. The requirement for repeat doses of NARCAN® (naloxone hydrochloride), however, will also be dependent upon the amount, type and route of administration of the narcotic being antagonized.

INDICATIONS NARCAN® (naloxone hydrochloride) is indicated for the complete or partial reversal of narcotic depression, including respiratory depression, induced by natural and synthetic narcotics, propoxyphene and the narcotic-antagonist analgesic pentazocine.
NARCAN® (naloxone hydrochloride) is also indicated for the diagnosis of suspected acute opiate overdosage.

CONTRAINDICATIONS NARCAN® (naloxone hydrochloride) is contraindicated in patients known to be hypersensitive to it.

WARNINGS NARCAN® (naloxone hydrochloride) should be administered cautiously to persons including newborns of mothers who are known or suspected to be physically dependent on opioids. In such cases an abrupt and complete reversal of narcotic effects may precipitate an acute abstinence syndrome.

The patient who has satisfactorily responded to NARCAN® (naloxone hydrochloride) should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary, since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride).

NARCAN® (naloxone hydrochloride) is not effective against respiratory depression due to non-opioid drugs.

Usage in Pregnancy Safe use of NARCAN® (naloxone hydrochloride) during pregnancy (other than labor) has not been established. Animal reproduction studies have not demonstrated teratogenic or other embryotoxic effects (See ANIMAL PHARMACOLOGY AND TOXICOLOGY). However, NARCAN® (naloxone hydrochloride) should be administered to pregnant patients only when, in the judgment of the physician, the potential benefits outweigh the possible hazards.

PRECAUTIONS In addition to NARCAN® (naloxone hydrochloride), other resuscitative measures such as maintenance of a free airway, artificial ventilation, cardiac massage, and vasopressor agents should be available and employed when necessary to counteract acute narcotic poisoning.

In an isolated report two patients with pre-existing ventricular irritability requiring lidocaine, and either isoproterenol or epinephrine for hypotension following cardiopulmonary bypass procedures, developed ventricular tachycardia or fibrillation when given NARCAN® (naloxone hydrochloride) I.V. at 9 and 14 hours, respectively, postoperatively for persistent unresponsiveness. Although a direct cause and effect relationship has not been established, NARCAN® (naloxone hydrochloride) should be used with caution in patients with cardiac irritability.

ADVERSE REACTIONS In rare instances nausea and vomiting have been reported in postoperative patients receiving NARCAN® (naloxone hydrochloride) in doses higher than that recommended; a cause and effect relationship has not been established.

DOSAGE AND ADMINISTRATION NARCAN® (naloxone hydrochloride) may be administered intravenously, intramuscularly, or subcutaneously. The most rapid onset of action is achieved by intravenous administration and it is recommended in emergency situations.

Since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride) the patient should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary.

USAGE IN ADULTS Narcotic Overdose—Known or Suspected The usual initial adult dose is 0.4 mg (1 ml) NARCAN® (naloxone hydrochloride) administered I.V., I.M. or S.C. If the desired degree of counteraction and improvement in respiratory function is not obtained immediately following I.V. administration, it may be repeated intravenously at 2 to 3 minute intervals. Failure to obtain significant improvement after 2 or 3 doses suggests that the condition may be due partly or completely to other disease processes or non-opioid drugs.

Post Operative Narcotic Depression For the partial reversal of narcotic depression following the use of narcotics during surgery, smaller doses of NARCAN® (naloxone hydrochloride) are usually sufficient. The dose of NARCAN® (naloxone hydrochloride) should be titrated according to the patient's response. Excessive dosage of NARCAN® (naloxone hydrochloride) may result in significant reversal of analgesia and increase in blood pressure. Similarly, too rapid reversal may induce nausea, vomiting, sweating or tachycardia.

For the initial reversal of respiratory depression, NARCAN® (naloxone hydrochloride) should be injected in increments of 0.1 to 0.2 mg intravenously at two to three minute intervals to the desired degree of reversal i.e., adequate ventilation and alertness without significant pain or discomfort.

Repeat doses of NARCAN® (naloxone hydrochloride) may be required within one to two hour intervals depending upon the amount, type (i.e., short or long acting) and time interval since last administration of narcotic. Supplemental intramuscular doses have been shown to produce a longer lasting effect.

USAGE IN CHILDREN Narcotic Overdose—Known or Suspected The usual initial child dose is 0.01 mg/kg body weight given I.V., I.M. or S.C. This dose may be repeated in accordance with the adult administration guideline. If necessary, NARCAN® (naloxone hydrochloride) can be diluted with sterile water for injection.

USAGE IN NEONATES Narcotic-induced depression The usual initial dose is 0.01 mg/kg body weight administered I.V., I.M. or S.C. This dose may be repeated in accordance with adult administration guidelines.

HOW SUPPLIED 0.4 mg/ml of NARCAN® (naloxone hydrochloride) for intravenous, intramuscular and subcutaneous administration.

Available in 1 ml ampuls in boxes of 10 and 100.

0.02 mg/ml of NARCAN® (naloxone hydrochloride) NEONATAL INJECTION for intravenous, intramuscular and subcutaneous administration.

Available in 2 ml ampuls in boxes of 10 and 100 ampuls.

ANIMAL PHARMACOLOGY AND TOXICOLOGY In the mouse and rat the intravenous LD_{50} is 150 ±5 mg/kg and 109 ±4 mg/kg respectively. In acute subcutaneous toxicity studies in newborn rats the LD_{50} (95% CL) is 260 (228-296) mg/kg. Subcutaneous injection of 100 mg/kg/day in rats for 3 weeks produced only transient salivation and partial ptosis following injections; no toxic effects were seen at 10 mg/kg/day for 3 weeks.

Reproductive studies including fertility, general reproductive performance, embryotoxicity, teratogenicity, and lactation did not show any abnormality in mice and rats at 10 mg/kg/day.

hi-lo® tracheal tubes*

A high volume, low pressure cuffed endotracheal tube that inflates with a minimum of air pressure. Creates a no-leak seal, usually of less than 25 cm. H_2O; avoids trauma to the tracheal wall.

Soft and pliant tubes have a true murphy tip, intubate easily. Water clear, the tube fogs on exhalation, an instant monitor of patient respiratory function. May be used orally or nasally.

Other trademarks of NCC: **holdtite™, variform*, ventrol*, suture rib™, versi-cath*, maxi-flex & vac™, RAE™.**

*Covered under one or more of the following patents, U.S. Pat. No's 3,625,793, 3,605,750, 3,508,554, 3,610,242, and patents pending.

†University of Pittsburgh

Ncc satin-cath™* & gluv set

This sterile, disposable gluv set has met with overwhelming acceptance.

The GENTLE-FLO® catheter has a SATIN-SLIP SURFACE™ that provides smooth, non-binding insertion into an endotracheal tube.

The paperbacked glove slips on easily, fits either hand and is easily removed when suctioning is complete. The set also contains a waterproof receptacle. Pull the marked tabs and it opens and locks in position, ready to use for the receipt of sterile water. Equipped with VACTROL® connector, catheter suction may be simply regulated from full on to off.

Available with catheters in all popular sizes. Packaged in a sterile peel-back paper pouch—50 sets/box.

pitt*† trach speaking tube

This speaking tube permits tracheostomy patients to converse. The emotional benefits are obvious.

The hi-lo* cuff inflates easily to avoid tracheal damage. This possibility is further removed because the clear tubing permits convenient bronchoscopic observation of the tracheal wall. The auxiliary air supply tube is to be connected to a humidified air oxygen outlet to achieve a speaking air flow.

Equipped with Eross Safety Straps and removable spacers and adjustable collar, the trach tube is adaptable to fit any adult patient. The suction port, which may be locked, allows for suctioning of the patient without removing the respirator and introducing a flexible fiberoptic bronchoscope, thus avoiding delays during this critical period.

Manufactured with the precision medicine must demand.

ANECTINE®
(succinylcholine chloride)
For controlled muscle relaxation adjunctive to anesthesia:

FLO-PACK® for prolonged relaxation

- instant-mix sterile powder interfaces with all major parenteral systems (vacuum or nonvacuum)
- each unit complete—no needle or syringe needed
- retains potency indefinitely
- no refrigeration required
- unbreakable, sterile plastic injection units of 500 and 1,000 mg

INJECTION for short-term relaxation

- a product of choice for intubation and other short procedures
- unique square bottle and bright yellow label for positive identification
- ready for immediate use
- 20 mg per cc . . . in 10 cc multidose vials
- flip-top cap for easy opening
- single or multiple use

ANECTINE®
(succinylcholine chloride)
THE LONG AND SHORT of surgical muscle relaxation

THIS DRUG SHOULD BE USED ONLY BY INDIVIDUALS FAMILIAR WITH ITS ACTIONS, CHARACTERISTICS AND HAZARDS.

DESCRIPTION: Anectine brand Succinylcholine Chloride is an ultra short-acting depolarizing type muscle relaxant. Chemically it is a di-quaternary base consisting of the di-chloride salt of the di-choline ester of succinic acid. It is a white, odorless, slightly bitter powder and very soluble in water. The drug is unstable with alkaline solutions, but relatively stable in acid solutions depending upon the concentration of the solution and the storage temperature. While solutions of succinylcholine chloride are sterilized by autoclaving, they should, nevertheless, be stored under refrigeration to preserve their potency.

INDICATIONS: Succinylcholine chloride is indicated as an adjunct to anesthesia to induce skeletal muscle relaxation. It may be employed to reduce the intensity of muscle contractions of pharmacologically or electrically induced convulsions.

CONTRAINDICATIONS: Succinylcholine is contraindicated for persons with a known hypersensitivity to the drug.

WARNINGS:

WARNING: SUCCINYLCHOLINE SHOULD BE USED ONLY BY THOSE SKILLED IN THE MANAGEMENT OF ARTIFICIAL RESPIRATION AND ONLY WHEN FACILITIES ARE INSTANTLY AVAILABLE FOR ENDOTRACHEAL INTUBATION AND FOR PROVIDING ADEQUATE VENTILATION OF THE PATIENT, INCLUDING THE ADMINISTRATION OF OXYGEN UNDER POSITIVE PRESSURE AND THE ELIMINATION OF CARBON DIOXIDE. THE CLINICIAN MUST BE PREPARED TO ASSIST OR TO CONTROL RESPIRATION.

Succinylcholine should not be mixed with short-acting barbiturates in the same syringe, or administered simultaneously during intravenous infusion through the same needle. Solutions of succinylcholine have an acid pH whereas those of barbiturates are alkaline in reaction. Depending upon the resultant pH of a mixture of solutions of these drugs, either free barbituric acid may be precipitated or succinylcholine hydrolyzed.

Usage in Pregnancy. The safe use of succinylcholine has not been established with respect to the possible adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential and particularly during early pregnancy unless in the judgment of the physician the potential benefits outweigh the unknown hazards.

PRECAUTIONS: Low levels of, or abnormal variants of plasma cholinesterase may be associated with prolonged respiratory depression or apnea following the use of succinylcholine. Low levels of plasma cholinesterase may occur in patients with severe liver disease or cirrhosis, severe anemia, malnutrition, severe dehydration, changes in body temperature, exposure to neurotoxic insecticides or those receiving antimalarial drugs. Succinylcholine should be administered with extreme care to such patients and dosage should be minimal. If low plasma cholinesterase activity is suspected, a small test dose of from 5 to 10 mg of succinylcholine may be administered, or relaxation may be produced by the cautious administration of a 0.1% solution of the drug by intravenous drip. Drugs which either inhibit plasma cholinesterase, such as neostigmine or phospholine iodide, or compete with succinylcholine for the enzyme, as does intravenous procaine, should not be given concurrently with succinylcholine.

Succinylcholine should be administered with great caution to patients with severe burns, those recovering from severe trauma, those suffering from electrolyte imbalance, those receiving quinidine, those who have been digitalized recently or who may have digitalis toxicity as serious cardiac arrhythmias or cardiac arrest may result. Great caution should be observed also in patients with pre-existing hyperkalemia or who are paraplegic, have suffered spinal neuraxis injury, or have degenerative or dystrophic neuromuscular disease, as such patients tend to become severely hyperkalemic when succinylcholine is given.

When succinylcholine is given over a prolonged period of time, the characteristic depolarization block of the myoneural junction may change to a non-depolarizing block which results in prolonged respiratory depression or apnea. Under such circumstances, small repeated doses of neostigmine may possibly act as an antagonist. A peripheral nerve stimulator (e.g., the Wellcome Peripheral Nerve Stimulator) may be used to ascertain the type of neuromuscular blockade. If a depolarization block is present both fast (tetanic) and slow (twitch) rates of nerve stimulation are well sustained, and post-tetanic facilitation is absent. If a non-depolarizing block is present there is post-tetanic facilitation and "fade" of successive stimuli on both fast (tetanic) and slow (twitch) rates of nerve stimulation.

Succinylcholine should be used with caution during ocular surgery and in patients with glaucoma. The drug should be employed with caution in patients with fractures or muscle spasm as the muscle fasciculations may cause additional trauma. Muscle fasciculations and hyperkalemia may be reduced by administering a small dose of a non-depolarizing relaxant. If other relaxants are to be used during the same procedure, the possibility of a synergistic or antagonistic effect should be considered.

During the past few years, reports have called attention to a fulminant syndrome, malignant hyperthermia, observed during anesthesia. Its etiology is not fully understood. Malignant hyperthermia occurs in genetically prone individuals of all ages and both sexes receiving potent anesthetics such as halothane, methoxyfluothane, cyclopropane and diethyl ether. It appears to develop irrespective of the concomitant use of a muscle relaxant, but may be triggered by succinylcholine. Because of the seriousness of this syndrome and the need for early effective treatment of the patient, it is suggested that the continuous monitoring of the temperature will serve as an aid to the early recognition of malignant hyperthermia.

ADVERSE REACTIONS: Adverse reactions consist primarily of an extension of the drug's pharmacological actions. Profound and prolonged muscle relaxation may occur, resulting in respiratory depression to the point of apnea. Hypersensitivity to the drug may exist in rare instances.

The following adverse reactions have been reported: bradycardia, tachycardia, hypertension, hypotension, arrhythmias, cardiac arrest, prolonged respiratory depression or apnea, hyperthermia, increased intraocular pressure, muscle fasciculation, postoperative muscle pain, myoglobinemia and excessive salivation.

MANAGEMENT OF ADVERSE REACTIONS: Apnea or prolonged muscle paralysis should be treated with controlled respiration.

The use of neostigmine to reverse a non-depolarization block is a medical decision which must be made upon the basis of the individual clinical pharmacology and the experience and judgment of the clinician. When neostigmine is used atropine should also be administered.

SUPPLIED: Injection, Multi-dose vials, 20 mg cc, 10 cc, boxes of 12 vials. Flo-Pack® Sterile Powder 500 mg and 1,000 mg, boxes of 12.

new flexible Fiber Optic

Laryngoscope

direct vision for difficult intubations

The first flexible fiberscope specifically for endotracheal intubations.

Portable, and with its own integral lighting system, the Flexible Fiber Optic Laryngoscope is inserted into the trachea under direct vision.

The articulating end-tip enables it to be directed into position for passage through the vocal cords. The scope then acts as a guide over which the endotracheal tube is passed.

When intubation is achieved, the scope is withdrawn leaving the tube in place.

The complete Flexible Fiber Optic Laryngoscope includes a 49 cm. flexible length, battery handle, 2 C cells, adjustable illumination, spare lamp and a special, foam-lined carrying case.

ANECTINE®

Low levels of plasma cholinesterase may occur in patients with severe liver disease or cirrhosis, severe anemia, malnutrition, severe dehydration, changes in body temperature, exposure to neurotoxic insecticides or those receiving antimalarial drugs. Succinylcholine should be administered with extreme care to such patients and dosage should be minimal. If low plasma cholinesterase activity is suspected, a small test dose of from 5 to 10 mg of succinylcholine may be administered, or relaxation may be produced by the cautious administration of a 0.1% solution of the drug by intravenous drip. Drugs which either inhibit plasma cholinesterase, such as neostigmine or phospholine iodide, or compete with succinylcholine for the enzyme, as does intravenous procaine, should not be given concurrently with succinylcholine.

Succinylcholine should be administered with great caution to patients with severe burns, those recovering from severe trauma, those suffering from electrolyte imbalance, those receiving quinidine, those who have been digitalized recently or who may have digitalis toxicity as serious cardiac arrhythmias or cardiac arrest may result. Great caution should be observed also in patients with pre-existing hyperkalemia or who are paraplegic, have suffered spinal neuraxis injury, or have degenerative or dystrophic neuromuscular disease, as such patients tend to become severely hyperkalemic when succinylcholine is given.

When succinylcholine is given over a prolonged period of time, the characteristic depolarization block of the myoneural junction may change to a non-depolarizing block which results in prolonged respiratory depression or apnea. Under such circumstances, small repeated doses of neostigmine may possibly act as an antagonist. A peripheral nerve stimulator (e.g., the Wellcome Peripheral Nerve Stimulator) may be used to ascertain the type of neuromuscular blockade. If a depolarization block is present both fast (tetanic) and slow (twitch) rates of nerve stimulation are well sustained, and post-tetanic facilitation is absent. If a non-depolarizing block is present there is post-tetanic facilitation and "fade" of successive stimuli on both fast (tetanic) and slow (twitch) rates of nerve stimulation.

Succinylcholine should be used with caution during ocular surgery and in patients with glaucoma. The drug should be employed with caution in patients with fractures or muscle spasm as the muscle fasciculations may cause additional trauma. Muscle fasciculations and hyperkalemia may be reduced by administering a small dose of a non-depolarizing relaxant. If other relaxants are to be used during the same procedure, the possibility of a synergistic or antagonistic effect should be considered.

During the past few years, reports have called attention to a fulminant syndrome, malignant hyperthermia, observed during anesthesia. Its etiology is not fully understood. Malignant hyperthermia occurs in genetically prone individuals of all ages and both sexes receiving potent anesthetics such as halothane, methoxyfluothane, cyclopropane and diethyl ether. It appears to develop irrespective of the concomitant use of a muscle relaxant, but may be triggered by succinylcholine. Because of the seriousness of this syndrome and the need for early effective treatment of the patient, it is suggested that the continuous monitoring of the temperature will serve as an aid to the early recognition of malignant hyperthermia.

ADVERSE REACTIONS: Adverse reactions consist primarily of an extension of the drug's pharmacological actions. Profound and prolonged muscle relaxation may occur, resulting in respiratory depression to the point of apnea. Hypersensitivity to the drug may exist in rare instances.

The following adverse reactions have been reported: bradycardia, tachycardia, hypertension, hypotension, arrhythmias, cardiac arrest, prolonged respiratory depression or apnea, hyperthermia, increased intraocular pressure, muscle fasciculation, postoperative muscle pain, myoglobinemia and excessive salivation.

MANAGEMENT OF ADVERSE REACTIONS: Apnea or prolonged muscle paralysis should be treated with controlled respiration.

The use of neostigmine to reverse a non-depolarization block is a medical decision which must be made upon the basis of the individual clinical pharmacology and the experience and judgment of the clinician. When neostigmine is used atropine should also be administered.

SUPPLIED: Injection, Multi-dose vials, 20 mg cc, 10 cc, boxes of 12 vials. Flo-Pack® Sterile Powder 500 mg and 1,000 mg, boxes of 12.

new flexible Fiber Optic

Laryngoscope

direct vision for difficult intubations

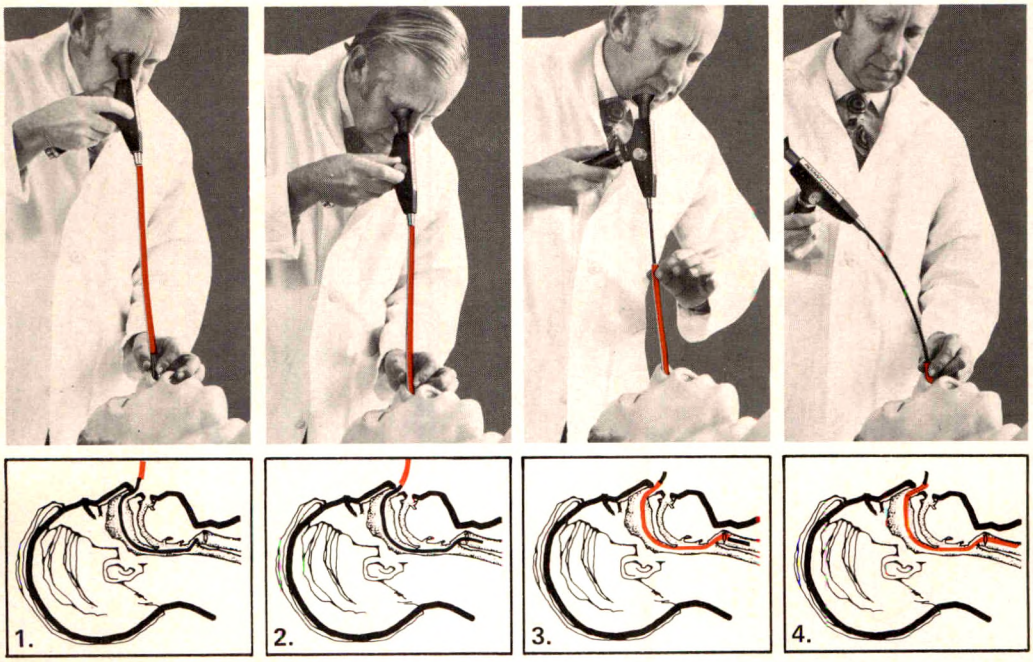
The first flexible fiberscope specifically for endotracheal intubations.

Portable, and with its own integral lighting system, the Flexible Fiber Optic Laryngoscope is inserted into the trachea under direct vision.

The articulating end-tip enables it to be directed into position for passage through the vocal cords. The scope then acts as a guide over which the endotracheal tube is passed.

When intubation is achieved, the scope is withdrawn leaving the tube in place.

The complete Flexible Fiber Optic Laryngoscope includes a 49 cm. flexible length, battery handle, 2 C cells, adjustable illumination, spare lamp and a special, foam-lined carrying case.



integral lighting, plus fiber optics forever eliminate "blind" intubations

1. Pass the flexible length through an endotracheal tube. The right hand controls end-tip deflection. The left hand introduces the scope through the nose, and advances it along the posterior wall of the pharynx and beyond the epiglottis.

Deflect the end-tip to see the larynx . . .

2. and pass it through the cords, into the trachea to a depth of about 5 cm.

The scope provides a clear, direct view of the internal anatomy as it travels along the respiratory tract.

3. When the end-tip is well in place within the trachea, simply advance the endotracheal tube. The scope acts as a stylet for the tube, making proper intubation a virtual certainty.

4. Remove the scope when intubation is completed.

Please rush ☐ product literature, ☐ research article reprints.

☐ I am interested also in a demonstration of the AO Flexible Fiberoptic Laryngoscope.

CALL FOR PAPERS

August 2, 1976—Deadline for submission of titles and abstracts. Application forms will be available May 1, 1976 from: John T. Martin, M.D., Chairman, Program Committee, Medical College of Ohio at Toledo, P. O. Box 6190, Toledo, Ohio 43614.

A Technic of General Anesthesia for Blepharoplasty and Rhytidectomy

HERZL KATZ, M.D.*
ROY C. MACHIDA, M.D.†
D. GARETH WOOTTON, M.D.†
ROBERT AMONIC, M.D.†

A series of 66 consecutive cases of blepharoplasty and rhytidectomy are reported, 60 of which were performed with a general anesthesia technic utilizing local anesthesia with epinephrine, in association with enflurane inhalation delivered via bilateral nasopharyngeal airways (BNPA). Six cases were not suitable candidates for the technic because of physical status or for anatomic reasons. The technic has the advantage of providing airway control without tracheal intubation, light depth of anesthesia, compatibility with epinephrine, and highly acceptable limits of intraoperative bleeding and postoperative hematoma.

LOCAL anesthesia with epinephrine and preoperative basal sedation is used in the majority of blepharoplasties and rhytidectomies. Frequently, however, because of patient restlessness during the lengthy procedure, IV hypnotic or narcotic supplementation is needed, with the associated danger of hypoventilation or loss of airway control in a poorly accessible field.

There appears to be reluctance to routinely use general endotracheal anesthesia because of the added anesthesia risks and dangers involved, and the concern about possible increased incidence of hematomas under the extensive skin flaps. Many patients, however, are concerned about being awake and suffering discomfort during the long procedure, which often is 3 to 4 hours in duration.

An optimum technic of general anesthesia for blepharoplasty and rhytidectomy should provide the following:

(1) Maintenance of an adequate airway
(2) Controllable light levels of anesthesia
(3) Anesthetic agents compatible with epinephrine
(4) Acceptable intraoperative blood loss
(5) Minimal postoperative hematoma formation
(6) Minimal bucking and straining
(7) Smooth emergence from anesthesia
(8) Minimal postanesthetic morbidity

In our hands, a technic utilizing local anesthesia with epinephrine in association with enflurane inhalation delivered through bilateral nasopharyngeal airways (BNPA) has proved successful. We report a series of 66 consecutive cases of combined blepharoplasty and rhytidectomy, of which 60 were judged suitable for this anesthetic technic.

FIGURE. BNPA, flexible connector, and elephant tubes are led over chin and chest. Sterile stockinette is placed over the connector.

PROCEDURE

The BNPA technic was first described in 1969 by Elam and associates.[1,2] Patients are monitored with precordial stethoscope, BP cuff, and continuous ECG. After an induction dose of barbiturate, 2 well-lubricated 26 French Rusch red-rubber nasopharyngeal airways with adapter preattached are gently and cautiously advanced through the nares and choanae and directed posteriorly and inferiorly along the floor of the nasopharynx. When advanced completely, the airway ends will be positioned just below the tip of the epiglottis. The anesthesia machine and anesthesiologist can be positioned at either side of the patient (figure).

A folded sheet or sandbag is placed longitudinally under the patient's back, for adequate neck extension; flexion or incomplete extension may cause the BNPA to kink and obstruct the airway. The adequacy of the airway can now be tested by turning the head from side to side and observing bag movement as an index of obstruction.

In approximately 90% of patients with the BNPA technic, it is possible to assist or control respirations as long as the glottis remains patent, because the tongue and soft pharyngeal structures collapse to form a seal about the tubes. Elam[1] demonstrated that the esophageal opening pressure of 15 to 25 cm H_2O exceeds the 10 to 20 cm H_2O bag pressure which will produce excess oral gas "pop-off," so that positive bag pressure can be applied and overflow gases vented orally with little danger of inflating the stomach.

Maintenance flows of N_2O-O_2 (2 L:2 L) and 1.0 to 2.5% enflurane are delivered; the actual concentration inhaled by the patient is less than this because of some air-mixing in the oropharynx. The surgeon infiltrates initially with a suitable local agent with epinephrine to a maximum of 100 μg, an amount safely compatible with enflurane; local epinephrine is injected again at appropriate intervals.[3] Systolic pressures are usually maintained in the 80 to 100 torr range.

Spontaneous respirations are usually adequate in volume, as measured by Vortex respirometer, and are assisted at intervals. If gross leaks are present, vaseline gauze may be used to seal the nares about the tubes. Constant monitoring of bag movement as evidence of airway patency is essential.

The patient is taken to the recovery room with the BNPA in place. Airways are well

tolerated, without bucking, until the patient is awake, usually within 15 minutes of arrival.

THE SERIES

Our series included 66 consecutive women who underwent both blepharoplasty and rhytidectomy. All patients were seen preoperatively and postoperatively, and 6 patients were omitted from the study as unsuitable candidates for the BNPA technic. Of these, 2 had histories of previous nasal surgery, one had moderate obstructive respiratory disease, and 3 had short, receding chins and limited head extension, suggesting that airway maintenance with BNPA would be difficult. We elected to intubate this group orotracheally immediately on induction.

Patients ranged in age from 43 to 67 years (mean 56); 88% were in the 43 to 64 age range. Fifty-six patients were ASA class I; 4 were in class II. All procedures were performed by the same group of physicians. Blood loss was estimated visually from drapes and sponges.

RESULTS

During our early experience, the level of anesthesia lightened precipitously and laryngeal spasm occurred in 4 cases. It was necessary to partially undrape the field and intubate orotracheally; an endotracheal tube should always be available for such an emergency. However, with more experience, this has not occurred in our last 35 consecutive cases.

Total anesthesia time ranged from 2½ to 5 hours; 83% of the cases were 3 to 4 hours in duration. We have had no episodes of gastric inflation, silent regurgitation, or aspiration clinically demonstrable during these lengthy procedures. Blood loss was estimated between 125 and 600 ml (mean 285 ml).

There were no hypotensive episodes, and no transfusions were required (table). The postoperative hematoma rate was 3.3% (2 patients); only one of these was returned to the operating suite for evacuation of extensive clots. Patients were uniformly grateful that they had been anesthetized for the procedure.

TABLE
Complications and Morbidity

	Number	Percent
Intubated intraoperatively	4	7
Hypotension	0	0
Excitement emergence	4	7
Epistaxis	0	0
Postoperative hematomas	2	3.3
Nausea	5	8
Vomiting	7	12
Headache	6	10

DISCUSSION

We do not use the BNPA technic in patients with a history of previous nasal surgery, severe nasal obstruction, nasal polyps or allergies, or patients with anatomically hazardous head and neck configurations, such as short or receding chins, bull-neck, or limited head extension, preferring to intubate these patients immediately on induction. Though we are well aware of the potential hazard, we have not had any problems with gastric inflation or silent regurgitation. As a rule, patients who desire this procedure are in good general health, ASA class I or II, although many are in the sixties age group. We do not accept ASA class III patients for this highly elective procedure.

As mentioned, the breathing bag must be watched *constantly* for evidence of airway obstruction and adequacy of ventilation volume. The surgeon must be cooperative in maintaining proper extension of the head. When necessary, the head must be turned gently to avoid dislodging the airways. Should there be any airway difficulties, the surgeon must be prepared to stand aside immediately so that the anesthesiologist can assess the problem and intubate if required. Close cooperation between surgeon and anesthesiologist is a necessity.

ACKNOWLEDGMENT

The authors thank Mrs. Nancy Brault and Mrs. Eleanor Rondelle, librarians, Saint John's Hospital; Mrs. Barbara Rydgren, Medical Records Department; and the Misses Rhoda Weiss and Glenna Webb for secretarial help.

Cardiovascular Dynamics After Large Doses of Fentanyl and Fentanyl Plus N_2O in the Dog

WEN-SHIN LIU, MD*
ARUN V. BIDWAI, MD†
THEODORE H. STANLEY, MD‡
JESUS ISERN-AMARAL, MD§
Salt Lake City, Utah‖

The effects of large doses of fentanyl (0.05 to 2 mg/kg) and fentanyl plus N_2O on cardiovascular dynamics were determined in 10 unpremedicated dogs breathing 100% O_2. Using computer analysis of the central aortic pulse-pressure curve, stroke volume (SV), cardiac output, heart rate (HR), peripheral vascular resistance (PVR), and systolic, diastolic, and mean arterial blood pressures (BP) were determined while fentanyl was being given at a rate of 0.3 to 0.44 mg/min. Fentanyl caused a dose-related decrease in HR, which was significant at 0.05 mg/kg. Cardiac output, PVR, and systolic, diastolic, and mean arterial BP were also decreased and SV increased. The latter changes became significant at 0.1 mg/kg for diastolic BP; 0.15 mg/kg for cardiac output and mean BP; 0.25 mg/kg for SV and systolic BP; and at 1.25 mg/kg for peripheral vascular resistance. Addition of N_2O after fentanyl did not significantly change any parameter, although SV, cardiac output, and HR were usually increased and PVR decreased.

These data demonstrate that, while large doses of fentanyl or fentanyl plus N_2O do alter cardiovascular dynamics in dogs, the changes appear to be less profound than those produced by equianalgesic doses of morphine. Our findings suggest that large doses of fentanyl-O_2 may be an attractive alternative to morphine-O_2 anesthesia in critically ill patients.

FENTANYL, 1-(2-phenethyl)-4-(n-propionylanilino)-piperidine, in doses of 0.02 mg/kg, has little effect on left ventricular dynamics in the neurally intact, blood-perfused dog heart.[1,2] In man, 10 μg/kg of fentanyl significantly increases stroke volume (SV) and cardiac index (CI).[3] These data suggest that large doses of fentanyl and O_2 may represent an attractive alternative to morphine and O_2 anesthesia for critically ill patients. However, while fentanyl has approximately 130 to 180 times the analgesic potency of morphine,[4,5] its amnesic properties have not been established. It is, therefore, difficult to know what dosages will be required for complete anesthesia in man, and what the cardiovascular effects of these doses will be if fentanyl is used as the sole anesthetic. This study was undertaken to investigate the cardiovascular effects of a range of high doses of fentanyl alone and fentanyl plus N_2O in the dog.

METHODS

Ten fasted, unpremedicated mongrel dogs, average weight 17 kg (range 15 to 22 kg),

served as experimental subjects. Each animal had an IV infusion of lactated Ringer's solution started in a foreleg prior to anesthesia, was induced and intubated after 5 to 10 mg/kg of sodium thiopental and 2 mg/kg of succinylcholine, and was ventilated with 100% O_2 at tidal volumes of 5 to 12 ml/kg with a volume-limited respirator. Respirations were controlled to maintain $Paco_2$ between 30 and 35 torr, as measured in aortic blood every 15 minutes.

Immediately after intubation, a Teflon catheter was implanted in the femoral artery through a small groin incision and threaded 20 to 35 cm to the central aorta. The aortic pressure catheter was attached via a Statham P23 Db arterial pressure transducer to a central digital computer substation (Tektronix® memory oscilloscope) in the laboratory. Warner's method of analyzing the central aortic pulse-pressure curve was used to determine cardiac output, SV, arterial BP and peripheral vascular resistance (PVR), and heart rate (HR).[6] Occasionally, additional 1 to 5 mg/kg doses of sodium thiopental and 1 mg/kg doses of succinylcholine were required to maintain anesthesia until the aortic catheter was in place. Following placement of ECG leads on the extremities and a 15-minute equilibration period, control (pre-fentanyl) measurements of HR, SV, cardiac output, SVR, and systolic, diastolic, and mean arterial BP were obtained. Fentanyl (0.06 mg/ml) was then administered IV as a continuous infusion at a rate of 0.3 to 0.44 mg/min in lactated Ringer's solution. Additional data were obtained following infusion of 0.05, 0.1, 0.15, 0.25, 0.5, 0.75, 1, 1.25, 1.5, 1.75, and 2 mg/kg of the drug. The inspired gases were then changed to 50% N_2O in O_2, and after a 20-minute equilibration period, a final set of data was taken. Data were analyzed for statistical significance using Student's paired *t*-test.

RESULTS

Changes in cardiovascular dynamics versus dose of fentanyl are given in the table. Fentanyl caused a dose-related increase in SV and decrease in HR, systolic, diastolic, and mean arterial BP, and peripheral vascular resistance. While HR was significantly decreased after 0.05 mg/kg of fentanyl, it took 0.1 to 0.25 mg/kg to produce significant changes in SV and arterial pressures and 1.25 mg/kg to significantly alter peripheral vascular resistance. Cardiac output was also reduced by fentanyl. The major proportion of the reduction occurred prior to 0.25 mg/kg. Additional fentanyl had little further effect on cardiac output.

Addition of 50% N_2O after 2 mg/kg of fentanyl did not significantly alter any cardiovascular parameter studied. However, most animals had small increases in HR, SV, and cardiac output and decreases in peripheral vascular resistance. In 3 dogs, addition of N_2O increased cardiac output by more than 500 ml/min. No dog experienced any arrhythmia either during fentanyl administration or after the addition of N_2O to the inspired mixture of gases.

DISCUSSION

Large doses of IV morphine (0.5 to 3 mg/kg) plus O_2 has little effect on myocardial dynamics and has, therefore, become popular as an anesthetic technic for critically ill patients undergoing cardiac and other major operative procedures.[7,8] However, hypotension,[8,9] hypertension,[9] increased blood requirements,[10] antidiuresis,[11] and incomplete amnesia[8] have been demonstrated to be disadvantages of morphine-O_2 anesthesia. Fentanyl, a potent, short-acting synthetic narcotic, also produces no detectable cardiovascular depression in doses equianalgesic to anesthetic doses of morphine,[1-3] and possesses the additional advantages of not causing histamine release and being easily reversible with naloxone.[2]

While the combination of fentanyl and droperidol, a butyrophenone, is reputed to cause minimal changes in myocardial contractility[12] and cardiovascular dynamics[13] and has achieved clinical acceptance as an anesthetic for critically ill patients, recent data suggests that droperidol in clinically used dosages significantly impairs left ventricular function.[1] On the basis of the above, large doses of fentanyl, as the sole anesthetic, plus O_2 has been advocated and seems reasonable as an alternative anesthetic technic to morphine-O_2 for critically ill patients.[2] However, the amnesic qualities of doses of fentanyl that are equianalgesic to morphine are unknown.

A study in preoperative patients comparing fentanyl (0.5 mg) with an equianalgesic dose of meperidine (500 mg), a drug not noted for its amnesic actions, found that the former resulted in significantly less amnesia than the latter.[14] This suggests that extremely large doses of fentanyl may be required to achieve amnesia when used as the sole anesthetic.

Our present study of the cardiovascular effects of 0.05 to 2 mg/kg of fentanyl in unatropinized dogs demonstrates that these enormous doses of fentanyl are associated with significant decreases in HR, cardiac output, arterial BP, PVR, and increases in stroke volume. While most of the parameters measured were progressively changed by increasing fentanyl dosages, almost all the decrease in cardiac output had occurred by the time 0.15 mg/kg was given. Thereafter, further decreases in HR were approximately compensated by simultaneous decreases in PVR and increases in stroke volume. This maintained cardiac output relatively constant.

The greatest decrease in output in any of the animals was 53%, and no animal had a systolic arterial BP <89 torr at any time. Addition of 50% N_2O after 2 mg/kg of fentanyl, instead of producing cardiovascular depression as was expected, did not significantly change any cardiovascular parameter measured. Indeed, SV, cardiac output, and HR were usually increased by N_2O. These data suggest that enormous doses of fentanyl are at least as, and possibly more, benign on canine cardiovascular dynamics as comparable doses of morphine.

Both morphine and fentanyl significantly decrease peak developed tension and the maximum rates of tension development and relaxation in proportion to dose in isolated saline-perfused rat heart muscle.[5] However, neither has a significant effect on myocardial contractility in blood-perfused hearts.[1,2,15] Although a detailed comparison of the cardiovascular effects of a range of comparable doses of morphine and fentanyl in intact animals has not been published, Schmidt and Livingston[16] found that 1 mg/kg of morphine injected IV produced marked decreases in canine HR and arterial BP, which lasted for 10 minutes.

Gardocki and Yelnosky[4] found that comparable doses of fentanyl (0.005 mg/kg) have no effect on HR and arterial BP in dogs, and that 0.01 to 0.04 mg/kg of fentanyl produced 15 to 30% less reduction in arterial BP than did 1/3 the equianalgesic dose of morphine (0.5 to 2 mg/kg) in dogs. Our data in this study show that 2 mg/kg of fentanyl reduces systolic arterial BP an average of 26%. Schmidt and Livingston[16] found that approximately half of a comparable dose of morphine (200 mg/kg) resulted in complete cardiovascular collapse and death in dogs.

The most immediate cardiovascular change produced by fentanyl in this study was bradycardia, HR being reduced an average of 25% after 0.05 mg/kg and an average of 52% after 2 mg/kg. Gardocki and Yelnosky[4] demonstrated that bradycardia produced by 0.04 mg/kg of fentanyl in dogs can be significantly decreased by premedication with atropine (1 mg/kg IV) or surgical vagotomy. They also showed that fentanyl-induced bradycardia can be completely reversed, once produced, with 0.1 to 0.5 mg/kg of IV atropine. This was not investigated in the present study, but in another investigation (unpublished data) we have shown that the above doses of atropine, given either as premedication or after administration of 1 mg/kg of fentanyl, while not completely preventing or reversing bradycardia, will significantly decrease it. Atropine also reduced decreases in cardiac output and arterial BP.

It could be reasoned that fentanyl in the doses used in this study would produce greater cardiovascular depression in unstimulated supine man than in intubated, minimally anesthetized dogs already subjected to the stimulation of a groin incision. That our animals may have been under some sympathetic stimulation is suggested by the high mean cardiac output (3.5 L/min or 203 ml/kg/min versus a normal of 139 ml/kg/min)[17] HR and arterial pressures during the control period. On the other hand, starting with animals already under sympathetic stimulation may have magnified the depressant effects of fentanyl in our study. Indeed, the greatest decreases in heart rate (−25%), cardiac output (−17%) and arterial BP (−12 to 17%) occurred during administration of the first 0.05 mg/kg of fentanyl. Subsequent increments of the drug produced much less change. In fact, it took all the rest of the 1.95 mg/kg of fentanyl administered to duplicate the initial percentage decrease in heart rate.

The cardiovascular effects and amnesic qualities of such doses of fentanyl as were used in this study are unknown in man. Stoelting and coworkers[3] found that 0.01 mg/kg of fentanyl produced no significant changes in mean arterial BP, HR, cardiac index, SV, and peripheral arterial resistance in supine, preoperative patients with valvular heart disease premedicated with fentanyl and scopolamine. This dose of fentanyl is equianalgesic to 2 mg/kg of morphine in the mouse.[4] Unfortunately, the analgesic and amnesic qualities of fentanyl were not

evaluated in Stoelting's patients.[3] However, they did show that addition of 60% N_2O significantly reduced mean arterial pressure, cardiac index, and HR, and suggested that the CI and BP reductions were primarily due to a decrease in HR.

It is interesting that although the changes were not significant, 50% N_2O tended to increase HR and cardiac output in our dogs after 2 mg/kg of fentanyl. Why N_2O acts differently in the dog after large doses of fentanyl than it does in man with smaller doses is unclear at this time.

OXYGEN AND MYOCARDIAL INFARCTION SIZE Interventions that improve the balance between myocardial oxygen supply and demand may reduce the size of a myocardial infarction. The present investigation sought to determine the influence of O_2 administration on myocardial infarction size following coronary artery ligation in the dog. The average ST segment elevation was reduced and CPK release less following coronary artery ligation breathing 40% O_2 as compared with breathing 20% O_2. It was postulated that increased oxygen availability to ischemic areas constituted the mechanism by which 40% oxygen reduced acute ischemic injury. Breathing pure O_2 was not found to be more beneficial than 40% O_2. An FIO_2 of 0.4 may be appropriate in the treatment of patients with acute myocardial infarction. *(Maroko PR, Radvany P, Braunwald E et al: Reduction of infarct size by oxygen inhalation following acute coronary occlusion. Anesthetic Considerations in Diffuse Bleeding Diathesis of Uncertain Origin

F. Y. DALAL, FFARCS*
E. J. BENNETT, FFARCS†
E. M. GRUNDY, FFARCS‡
S. YOUNES, MD§
E. ORFEI, MD‖

This is a report of a case of a diffuse bleeding tendency in a pregnant woman who presented for emergency splenectomy with a tentative diagnosis of thrombotic thrombocytopenic purpura. The influence of multiple organ dysfunction in the selection of appropriate monitors and the anesthetic technic in such cases are complex.

A PATIENT for emergency surgery with bleeding diathesis is a major anesthetic problem. Disseminated intravascular coagulation (DIC) and thrombotic thrombocytopenic purpura (TTP) are examples of two such conditions. Following is a report of a patient with a bleeding diathesis, tentatively diagnosed as TTP on our clinical and hematologic findings. In TTP, the basic problem is multiple organ failure due to hyaline thrombus formation in the arterioles and capillaries.[1] Until recently, TTP was almost invariably fatal.[2] With the observation that splenectomy (in addition to massive doses of steroids, heparinization, and antiplatelet-aggregating drugs such as aspirin and dipyridamole) has improved the prognosis significantly, anesthesiologists can expect to be confronted more frequently with such patients.[3-5] On the other hand, patients with DIC may present for control of bleeding in certain obstetric emergencies such as abruptio placentae, prostatic surgery, or after brain, liver, or lung damage.[6-8] The anesthetic literature is devoid of any guidelines for the rational management of such patients and is the reason for this report.

CASE REPORT

A 22-year-old Caucasian woman was admitted to another hospital with a presumptive diagnosis of hemolytic anemia. After 5 days, she was transferred to Loyola University for evaluation and treatment and was found to be 20 weeks pregnant. A tentative diagnosis of TTP was entertained on the basis of low platelet count, hemolysis, changing mental status, fever, and hematuria. Examination revealed splenomegaly,

Blood film on 11/18 showed the cells to be normocytic, normochromic histiocytes 3+, microspherocytes 2+, platelets markedly decreased. Sternal marrow: hypercellular 3+. Megakaryocytes: adequate to increased. Erythropoiesis: normoblastic. Urinalysis: blood, 2+; bacteria, 2+; albumin, 3+, WBC, clumps; RBC, 2-3 HPF. Chest x-ray: pulmonary infiltrates; changes consistent with pulmonary edema. ECG: within normal limits; sinus tachycardia. EEG: diffuse encephalopathy.

multiple ecchymoses over both extremities, bleeding gums, and a small left retinal hemorrhage in a stuporous patient responding only to painful stimuli, but without focal neurologic deficit. X-ray revealed pulmonary congestion with rhonchi and rales over both lung fields on auscultation. Laboratory, ECG, x-ray and EEG reports are shown in table.

Digitalis and diuretics had been started earlier, to which was added acetylsalicylic acid 900 mg; methylprednisolone 300 mg; dipyrimadole 100 mg; each 6 hourly via nasogastric tube.

Anesthetic Management.—The patient was premedicated with 0.4 mg of atropine IV and then preoxygenated for 5 minutes. Anesthesia was induced with 10 mg of pancuronium bromide followed by 150 mg of thiopental; cricoid pressure was exerted until endotracheal intubation had been achieved. Maintenance was with N_2O-O_2 (3:3) and a supplement of 2 ml of Innovar®. Frothy material was present on endotracheal suctioning and central venous pressure (CVP) was 22 cm H_2O. In view of this, chlorpromazine was given to a total of 22.5 mg. By the end of the 2-hour operation, the blood loss was partly replaced with packed cells, the CVP had fallen to 11 cm H_2O, and 130 ml of urine had been produced. Postoperatively, she was ventilated at an F_{IO_2} of 0.5 to maintain a P_{aO_2} >100 torr.

The following morning she was not fully conscious; her wound continued to ooze, she had bloody nasogastric aspirate, and had received 4 units of packed cells. As she then started to lose blood vaginally, labor was induced by membrane rupture and pitocin infusion. Shortly thereafter, an 800-gm fetus was born, surviving for 7 hours. The placenta was normal, and neither blood studies nor autopsy revealed any fetal abnormalities.

By the 2nd postoperative day, she had improved sufficiently to permit spontaneous ventilation and subsequent extubation. She now responded to both tactile and verbal stimuli. On the 3rd postoperative day, improvement continued, bleeding started to abate, and the platelet count rose daily to 120,000/cu m on the 7th day. By the 10th day, she was transferred to the original hospital.

Histopathology.—The spleen (315 gm) was considerably enlarged. The parenchyma was uniformly violaceous, with few discernible follicles. The splenic artery and vein were patent. Numerous follicular and penicillar arteries were found to be occluded by microthrombi. The red pulp had a few foci of hematopoiesis with megakaryocytes. These morphologic changes were interpreted to represent intravascular coagulation, suggestive of thrombotic thrombocytopenic purpura.

DISCUSSION

The symptom pentad of TTP[3] includes: (1) thrombocytopenic purpura, (2) hemolytic anemia, (3) changing mental status, (4) fever, and (5) renal involvement. A clinical diagnosis of TTP could not be positively differentiated from DIC from some other cause in this patient. Some features, common to both diseases, such as intravascular coagulation and microthrombi, causing multiple organ failure, are worthy of anesthetic consideration.

Preoperatively, measures to bring such patients to optimum condition include:

(1) Control of cardiac failure by digitalis and diuretics. In addition, peripheral vasodilation will benefit the patient by its effect as internal phlebotomy, possible improvement of renal perfusion, and by reducing the tendency to "sludging" and further thrombosis.

(2) Maintenance of adequate tissue oxygenation, which may be difficult in the presence of pulmonary insufficiency, low cardiac output, and low hemoglobin, some of which is free in the plasma and not contributory to O_2 transport. The pulmonary insufficiency from the multiple infarcts and incipient pulmonary edema may be helped by CPPB or CPAP, which may produce a rise in arterial O_2 tension. While this must be balanced against hypotension produced by the reduction in venous return, it may possibly improve both oxygenation and cardiac output.[9,10]

(3) Monitoring should include blood pressure, CVP, and possibly left atrial or pulmonary wedge pressure via a 4-channel Swan-Ganz catheter for combined right atrial and pulmonary wedge pressure monitors, as both sides of the heart may be in failure because of microemboli; in addition, it provides access to left atrial (arterial) blood for blood-gas analysis and can be used for all blood sampling, avoiding the risks of hematoma following venipuncture and preserving veins for the inevitable transfusions. Arterial punctures or cannulation in the presence of thrombotic processes may be open to criticism if the patient is not adequately heparinized.

(4) Blood volume should be restored cautiously, with full monitoring of blood pressure, CVP, urine output, and left atrial pressure. It must be borne in mind that platelets may accelerate the disease process, especially in the absence of heparinization; fresh blood may be contraindicated, but fresh frozen plasma is platelet poor and frozen red cells are platelet free.

(5) Fluid and electrolyte imbalance may be aggravated by renal failure and by the administration of steroids. Renal involvement occurs early, both as a result of the disease process and precipitation of the free hemoglobin in the plasma and in the renal tubules, the severity varying from microscopic hematuria to anuria. Alkalinization, diuretics, vasodilators (perhaps a specific renal vasodilator such as dopamine) should be considered. Dextran 70 may have a special place, as it acts by coating both vessels and platelets to prevent platelet aggregation, which is the initial process in thrombus formation.

(6) Serum K^+ values may be high from both hemolysis and renal involvement, and the use of a depolarizing agent such as succinylcholine may precipitate ventricular arrhythmias and even cardiac arrest.[11] However, as most such cases are seen on an emergency basis, rapid relaxation and intubation are necessary to minimize the risk of aspiration of gastric contents and should be intense enough to permit atraumatic insertion of the endotracheal tube, essential in a patient with hemorrhagic diathesis. It has been shown that 0.15 mg/kg of pancuronium achieves good intubating conditions within 30 seconds,[12] and this, combined with cricoid pressure (Sellick's maneuver), was the technic used here.

(7) Fibrinolysis is either primary or secondary to DIC and extremely difficult to differentiate. Hence, administration of epsilon-aminocaproic acid (Amicar®), the drug of choice for primary fibrinolysis, is not recommended unless it is given IV after a dose of 0.5 mg/kg of IV heparin. If Amicar is given to patients thought to have primary fibrinolysis, who had in fact DIC, disastrous thromboembolic complications can occur.[13] In most cases, DIC can be successfully treated by restoring blood volume, preferably with fresh blood, and by maintaining tissue perfusion.

Most pregnancies in such cases terminate by stillbirth or abortion, but live births (3/10) have occurred, with the neonate showing no abnormalities.[14] It should be mentioned that septic abortion with renal failure mimics TTP clinically, and evacuation of the uterus should be considered if there is no improvement in the clinical condition of the patient.

EPILOGUE

This patient became pregnant again and delivered a normal 3030 gm male child on 1/30/75 without problems. Her hematologic profile was normal.

PREGNANCY TEST Each year more than 12 million women of child bearing age are admitted to US hospitals. The possibility of early pregnancy should be considered in these patients prior to medical or surgical care. However, a survey of 224 hospitals with 200 beds or more revealed routine pregnancy tests were performed by only 3 per cent of private and municipal hospitals, 20 per cent of hospitals for the mentally retarded and by no psychiatric hospitals. A pregnancy test is simple and inexpensive and easily performed on the urine samples collected on admission. Such a test should be performed on all women of child bearing age especially if they are scheduled for surgery or radiographic investigation. *(Laubach GE Wilchins SA: Routine pregnancy test on admission to hospital. Am J Ob Gyn 123:691-694, 1975)*

"Pentazepam" (Pentazocine + Diazepam) Supplementing Local Analgesia for Laparoscopic Sterilization

J. ANTONIO ALDRETE, MD, MS*
SHIRLEY T. TAN, MD†
DONALD J. CARROW, MD‡
MARY K. WATTS, CRNA§
Louisville, Kentucky‖

Salpingectomy by laparoscopy in 200 healthy outpatients employed local analgesia and "pentazepam" (pentazocine 90 mg and diazepam 30 mg in 250 ml of 5% D/W) as anesthesia. Patients received no premedication, ventilated spontaneously, without tracheal intubation, but were given nasal O_2 at 3 L/min throughout the procedure. N_2O was used for abdominal insufflation, and the abdominal pressure and Trendelenburg position were restricted to less than 20 cm H_2O pressure and 30°, respectively. Changes in arterial blood gases measured in 12 patients were unremarkable. Prolonged recovery, unsatisfactory surgical conditions, tachycardia, nausea and vomiting were infrequent.

SALPINGECTOMY through a laparoscope has become a common sterilization procedure. Surgically, this appears a relatively simple procedure, and large series have been reported[1,2] with few complications.

The high demand for this endoscopic procedure and its apparent simplicity have encouraged its consideration for ambulatory patients. However, from the anesthetic point of view, it is by no means a minor procedure. The insufflation of a highly diffusible gas, commonly CO_2, within the abdominal cavity, to separate the abdominal wall from its contents, brings about hypercarbia[3,4] and its subsequent hemodynamic and metabolic effects. Even if CO_2 is substituted for N_2O, the elevated intraabdominal pressures required to attain the desired operative conditions exert undue pressure on the diaphragm; in addition, if the frequently used Trendelenburg position is extreme, these factors combined would produce marked impairment of ventilation.[5]

To assure proper respiratory function during this time and prevent the possible dangers of regurgitation and aspiration of gastric contents, endotracheal intubation has been recommended almost routinely. This technic, along with the use of muscle relaxant drugs and other longer-lasting anesthetic agents, appears to be overtreatment for patients who in a few hours will be returning home.

The foregoing considerations, and the desire for an alternative that would offer anesthetic safety with proper operative conditions, led us to evaluate pentazepam, a combination of the analgesic pentazocine with

the tranquilizer-amnesic diazepam, which, jointly used with local analgesia, would provide the expected conditions.

METHODS

This study includes 200 women between the ages of 22 and 43 years, all within ASA physical status I, electively scheduled for outpatient bilateral laparoscopic salpingectomy. None had a history of pelvic inflammatory disease or of lower abdominal surgery. A physical examination, chest x-ray, urinalysis, hemoglobin, and blood count were performed the day before the procedure. Patients were instructed not to drink or eat anything after midnight and were given a complete explanation of the procedure.

Admission to the hospital was scheduled for 0700 hr, and soon thereafter patients were taken to the operating room. An IV indwelling catheter was inserted, with lactated Ringer's solution. Monitoring was by precordial stethoscope, blood pressure cuff, and bipolar ECG. No premedication was given.

After obtaining initial values of heart rate, arterial blood pressure, and respiration, the pentazepam solution, consisting of pentazocine and diazepam (90:30 mg) in 250 ml of 5% D/W, was initiated as previously described[6] at a rate of 30 ml/min. This rate was maintained until patients closed their eyes spontaneously and appeared to be in deep sleep, though they were able to follow commands (take a deep breath, open your eyes, etc) or responded to severe painful stimulation. The remaining solution was then infused at a rate of 4 ml/min, until the moment of cauterization of the second uterine tube, at which time it was stopped.

Even before patients closed their eyes completely, but when signs of somnolence were seen, they were placed in a modified lithotomy position and their abdomen and vagina were scrubbed with soap and antiseptic solutions. A cervical suction cannula was introduced and the bladder emptied by catheterization. After draping, 6 ml of 1% lidocaine solution was injected in the lower rim of the umbilicus and underlying tissues.

Operation was usually started before 0800 hr. While lifting up the anterior abdominal wall, the surgeons inserted a Verres cannula into the abdominal cavity, and N_2O was initially insufflated until the abdomen appeared moderately distended. A 10-mm trochar was then introduced through which a Wolf laparoscope was passed after enough N_2O was insufflated to obtain adequate visualization but never to exceed 20 cm H_2O pressure within the abdomen, the total amount of N_2O insufflated ranging from 6 to 9.5 L. At this time, the patient was placed in a 20° Trendelenburg position. Oxygen (3 L/min) was administered by nasal prongs and vital signs were monitored throughout.

At the completion of the surgical procedure, patients were taken to the recovery room, evaluated by means of the Postanesthetic Recovery (PAR) Score,[7] and kept under close supervision until their discharge to the gynecologic outpatient recovery unit, remaining there until 1400 hr. Initially, to evaluate the effects of this technic on respiratory function, arterial blood gases and pH were measured in 12 patients.

In some cases when unsatisfactory conditions were noted, the anesthesia was supplemented by intermittent 25-mg doses of sodium thiopental or 50% N_2O-O_2 inhalation by mask. In the event of surgical complications requiring laparotomy, endotracheal intubation was performed with the aid of muscle relaxants and conventional anesthetic technics followed. All anesthetics were administered by either anesthesiology residents or nurse anesthetists under the supervision of staff anesthesiologists.

RESULTS

The mean age of the patients was 27.8 years and average weight was 56.4 kg. The average anesthetic and operative time was 39.4 and 24.8 minutes, respectively.

Satisfactory operative conditions with pentazepam and lidocaine alone were obtained in 176 patients. In these, an average of 142 ml of pentazepam solution was required to obtain the neuroleptic state similar to that observed with the administration of Innovar®. In 24 patients, the entire 250 ml was given.

Sodium thiopental had to be administered in 10 cases, and more diazepam (5 to 10 mg IV) in 34 others. In addition, N_2O was used as an adjuvant in 4 patients.

Untoward Reactions.—Tachycardia exceeding 25% of the preanesthetic heart rate was noted in 12 patients (5%), premature ventricular contractions and hypotension were seen only once each (0.5%) in sepa-

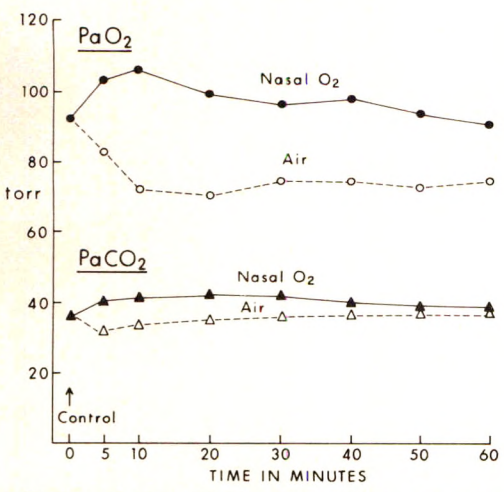

FIGURE. Average blood gas analysis in two groups of six patients each, breathing air and nasal oxygen.

rate patients. The former was treated with 60 mg of lidocaine HCl by IV bolus and the latter with fluid administration. Prolonged recovery (exceeding 120 minutes) was observed in 8 cases (4%). Nausea and vomiting occurred in 10 patients (5%).

The average recovery room stay was 57 minutes, with mean PAR scores at arrival of 8.08, all patients achieving scores of 10 before being discharged to the ward.

Because of surgical complications, 6 patients were hospitalized, 4 having undergone laparotomies either at the time or within 24 hours of the laparoscopy. One patient suffered a small skin burn from the cautery.

Blood-Gas Analysis (figure).—In the first group of 6 patients allowed to breathe room air, a decline of Pao_2 was noted during the first 30 minutes of the procedure. This, however, was prevented in the subsequent 6 patients, in whom nasal O_2 was administered at the rate of 3 L/min. Changes in CO_2, pH, and bicarbonate were not significant.

The mean postanesthetic scores at recovery-room arrival and progress to discharge are shown in the table.

DISCUSSION

In view of current trends, it is likely that bilateral salpingectomy will be increasingly frequent for permanent sterilization. Use of the laparoscope has greatly facilitated this operation, with minimal tissue injury.

It remains a challenge to the anesthesiologist to develop a technic that will avoid patient discomfort and pain and permit satisfactory surgical conditions without sacrificing patient safety. For socioeconomic reasons, an outpatient basis is also a desirable factor. (In other words, let us not give a 6-hour anesthetic for a 30-minute operation.) In this spirit, the technic described, which preserves adequate respiratory exchange without the need of endotracheal intubation, was developed. This maneuver, though safe in most instances, carries a certain morbidity and requires muscle relaxation and/or a deep level of anesthesia.

We previously reported the application of pentazepam as a supplement to local analgesia for laryngoscopy,[8] bronchoscopy, ventriculojugular shunt revision,[6] and inguinal herniorrhaphy[9] in elderly patients. Also, semiawake poor-risk patients with full stomach were intubated endotracheally with satisfactory results.[6] Other authors have used

TABLE
Postanesthetic Recovery Scores in Patients Undergoing Laparoscopic Tubal Ligations

Score	Arrival	15 minutes	30 minutes	60 minutes
Number of patients	200	200	184 (92)	160 (80)
10	58 (29)	105 (52.5)	151 (82)	143 (89.4)
9	63 (31.5)	54 (27)	12 (6.5)	8 (5)
8	39 (19.5)	19 (9.5)	9 (5)	1 (0.6)
7	22 (11)	12 (6)	4 (2.2)	8 (5)
6	10 (5)	2 (1)	8 (4.3)	0
5	8 (4)	8 (4)	0	0

this combination for minor gynecologic procedures,[10] as a supplement to regional anesthesia,[11] and for cardiovascular surgical procedures.[12]

Throughout these observations, the following pharmacologic advantages appear evident: minimal hemodynamic alterations, with no change of heart rate; moderate analgesia; excellent amnesia; and adequate sedation. A certain degree of respiratory depression can occur in cases of excessive dosage; however, this is usually compensated by surgical stimulation or can be easily antagonized by the administration of the analeptic, doxapram HCl. Overdosage can also result in prolonged recovery and occasionally in nausea and vomiting.

In the event of inadequate analgesia and sedation, small doses of diazepam, thiopental, or inhalation of N_2O were enough to achieve quasi-ideal conditions. This fact warrants the need for an experienced anesthesiologist at "the head of the table," and we would not advise its use without vigilant attention to the patient.

The high percentage of patients arriving at the recovery room with PAR scores of 10 indicates the alertness of these patients at this moment, most of whom could have been sent directly to the ward (table).

The amnesic properties of diazepam are invaluable, since the majority of patients barely remembered the initiation of the venoclysis and had no recall of what went on during the procedure, though they were able to communicate with the anesthesiologist. Though sedation was satisfactory, pharyngeal and laryngeal reflexes were maintained active, with patients either swallowing or coughing whenever salivary secretions were present.

The fact that premedication was not necessary saved time, expense, and discomfort to the patient, permitting faster recovery. As before,[6] we feel that if specific premedication is required for a technic to be effective, that technic is not completely dependable.

The apparent effectiveness of pentazepam for this operation may be due to the close adherence to the following guidelines agreed to by the surgeon-anesthesiologist team:

1. Consider only healthy women, within ASA class I.
2. Avoid CO_2 for insufflation.
3. Limit intraabdominal pressure to 20 cm H_2O.
4. Limit the operating time to 40 minutes.
5. Limit the Trendelenburg position, when needed, to 30° incline.

If any of these standards cannot be followed, we recommend other conventional anesthetic technics.[3-5]

By following these guidelines some other complications such as pneumothorax,[13] narrowing of pulse pressure due to large-vessel compression,[5] and occasional sore throat[14] will also be prevented. Hypercarbia and hypoxemia, noted in other studies[3,4,15,16] also can be avoided.

The need for O_2 supplementation in these procedures was also substantiated in a study by Baratz and Karis,[15] who noticed that even intubated patients undergoing laparoscopy with controlled ventilation needed to breathe at least 50% O_2 to maintain adequate Pao_2.

POSTOPERATIVE PAIN The efficacy of transcutaneous electrical stimulation in alleviating acute pain following abdominal or thoracic operations was evaluated in a prospective study. Forty-seven of 61 patients (77 per cent) experienced pain relief with transcutaneous electrical stimulation. Of these, 15 patients experienced complete pain relief and required no analgesic medication. Most were able to cough and breath deeply without significant pain during stimulation. Thirty-two of 39 patients (83 per cent) experienced no pain relief with mock stimulation. Transcutaneous electrical stimulation may serve as a useful adjunct to the postoperative alleviation of pain without the depressant or addictive hazards present with narcotics. *(VanderArk GD, McGrath KA: Transcutaneous electrical stimulation in treatment of postoperative pain. Am J Surg 130:338-340, 1975)*

MECONIUM ASPIRATION A retrospective study of 125 infants born through meconium stained amniotic fluid was performed. Forty-three newborns developed respiratory distress and 8 died. Of 97 infants receiving tracheal suction in the delivery room only 27 developed respiratory distress and 1 died. In contrast, 16 of 28 patients not receiving immediate tracheal suction developed respiratory distress and 7 died. Steroids and antibiotics did not alter the outcome. Immediate tracheal suction and removal of meconium are important in the management of infants born through meconium stained amniotic fluid. *(Ting P, Brady JP: Tracheal suction in meconium aspiration. Am J Ob Gyn 122:767-771, 1975)*

Survival Following Massive Pulmonary Hemorrhage Complicating Pulmonary Embolectomy: A Case Report

STUART B. WOLLMAN, MD*
LAWRENCE G. KUSHINS, MD†
New Hyde Park, New York‡

Continued employment of extracorporeal circulation provides for adequate oxygenation despite massive pulmonary hemorrhage. However, this modality requires continuing heparinization, which seems to preclude control of the hemorrhage. The longer bleeding persists, the more the pulmonary damage. Further, the problems of massive volume replacement will be added to this catastrophe. The authors believe that rapid discontinuance of extracorporeal bypass, reversal of heparinization with protamine, aggressive pulmonary suctioning, and alternate ventilation with 100% O_2 were responsible for their good result. Arterial hypoxemia was avoided despite pulmonary suction yielding 1500 ml in 17 minutes.

MASSIVE pulmonary hemorrhage has been reported to complicate pulmonary embolectomy when pulmonary circulation is reestablished. Of 8 reported cases of acute pulmonary hemorrhage,[1-3] only 1 patient survived. We are presenting the case of a second survivor, with a discussion of this entity and of therapy utilized in successful treatment. Although others[1,3] have minimized the role of reversal of heparinization with protamine, the dramatic response of our patient to this measure should be brought to the attention of cardiovascular surgical teams.

PATIENT HISTORY

A 37-year-old man suffered a ruptured spleen, fractured pelvis, lacerated left kidney, and multiple fractures of his left lower rib cage in an automobile accident on November 12, 1974, undergoing a splenectomy and repair of the lacerated kidney on that date. Postoperatively, his pulmonary status was a major problem, with extensive consolidation of the left lung field on x-ray. Pao_2 on room air was 34 torr on the 2nd postoperative day. He was treated with 100% O_2 by face mask, bringing his Pao_2 to 54 torr. He rapidly improved in the next 24 hours, so that FIO_2 was gradually reduced to 0.45, with Pao_2 in the range of 60 to 70 torr. On the 8th postoperative day, his Pao_2 on room air was 66 torr.

The possibility of fat embolism was treated with 1 gm of IV methylprednisolone sodium succinate NF on 2 successive days, although no diagnosis was proven. Heparin (5000 units) had been given subcutaneously twice a day as prophylaxis for the prolonged bed rest contemplated in the treatment of his pelvic fractures, starting on November 15 and continuing for 2 weeks. On November 28, 1974, following ambulation, the patient developed diaphoresis, tachycardia, hypotension, and fever (39.4 C). He complained of "tight" precordial chest pain. The ECG exhibited inverted T waves over the precordium. A lung scan

Paper received: 5/19/75
Accepted for publication: 8/7/75

showed a right upper lobe defect. Pulmonary angiography demonstrated a saddle embolus in the main pulmonary artery as well as right upper lobe and left middle lobe involvement. After a total of 26 hours without improvement, he was taken to the operating room for pulmonary embolectomy and clipping of the inferior vena cava.

On arrival in the operating room, vital signs were temperatures 39.4 C, pulse 132 bpm, respiration 28/min, BP 90/60 torr. CVP was 20 cm H_2O. Because of his precarious cardiovascular status, ketamine was used for induction and pancuronium for endotracheal intubation. Blood gases, with the patient breathing 100% O_2 via a semiclosed anesthesia system, were pH 7.40, $Paco_2$ 33 torr, and Pao_2 129 torr. Anesthesia was maintained with 2% fluroxene in O_2. After heparinization with 300 units/kg, extracorporeal bypass via a Bentley membrane oxygenator and Sarnes pump was instituted. The ascending aorta was cannulated and the venae cavae were cannulated via the right atrium. Moderate hypothermia to 33 C was induced. Two percent fluroxene, 2% CO_2, and 96% O_2 were administered via pump.

Upon opening the pulmonary artery, multiple clots were found in the main, right, and left pulmonary arteries and their lobar branches. Both lungs were severely blanched. Pulmonary embolectomy was performed with forceps, Foley catheter, pulmonary massage, and suctioning. Upon closure of the pulmonary artery and institution of partial bypass, both lungs were noted to be rigid and not expanding with ventilation. Almost immediately, massive amounts of bloody fluid were noted in the endotracheal tube.

Rapid IV administration of 0.25 mg of digoxin, 40 mg of furosemide, and 1 gm of hydrocortisone produced no reduction in hemorrhage. Upon noting 1500 ml of suctioned blood in a period of 17 minutes, extracorporeal bypass was abandoned and 4 mg/kg of protamine was administered. Hemorrhage stopped almost immediately. Sixty minutes elapsed between heparinization and the start of protamine administration. Blood gases drawn during this episode and the subsequent half hour showed Pao_2 ranging from 160 to 285 torr. Ventilation was with 100% O_2 during this period except during endotracheal suction. Mild acidosis was treated with 89.2 mEq of $NaHCO_3$. Rewarming had commenced with closure of the pulmonary artery, and the patient's rectal temperature was 36 C when bypass was concluded.

Ligation of the inferior vena cava and operative closure were uneventful. Postoperative chest x-rays initially revealed "a left lower lobe infiltrate, a small left pleural effusion, atelectasis of the right base, and an infiltrate of the right cardiophrenic angle." Postoperative arterial blood gases showed steadily decreasing alveolar:arterial differences in O_2 levels. Follow-up chest x-ray showed steady improvement, and no further pulmonary embolization or hemorrhage was evidenced. The patient's most persistent problem was phlebitis of the left leg, which was treated with heparin on the 5th postoperative day and later changed to sodium warfarin. He was discharged on the 23rd postoperative day.

DISCUSSION

The etiology of massive pulmonary hemorrhage following pulmonary embolectomy is unclear. Common to all cases is a period of hypotension and pulmonary hypoperfusion with damage to pulmonary capillaries, leading to hemorrhagic pulmonary infarction when blood flow is reestablished following embolectomy. While it is not clear from the literature, reports of the use of Carlens endobronchial tubes to isolate unilateral pulmonary bleeding[1] suggest this complication to be the result of local injury due to the embolus, although our patient showed no evidence of unilateral hemorrhage. This problem has occurred with both short[1] and long[2,4] periods between embolization and embolectomy, with a high incidence of this problem expected in the "chronic" embolectomy patient.[4]

Delayed pulmonary hemorrhage has been reported following embolectomy for chronic recurrent emboli.[4] However, this occurred as a late complication, hours after operation, and was of a lesser magnitude with a favorable outcome. The use of cardiopulmonary bypass and heparinization is not standard for the removal of thrombi in "chronic" embolectomy, and when pulmonary hemorrhage has been reported in the absence of bypass and heparin, it has been less severe and survival is more common. Heparinization appears to greatly increase the severity of postembolic pulmonary hemorrhage, although this entity has been reported in the absence of extracorporeal bypass in 1 case.[3]

Makey's group[1] postulated corticosteroid-related abnormalities, since their 2 cases

and that published by Castleman[2] were either on chronic steroid therapy or showed adrenal pathology at necropsy. However, 5 subsequent cases, including the single previous survivor described by Couves and associates,[3] yielded no hint of steroid abnormalities.

Treatment of massive pulmonary hemorrhage following pulmonary embolectomy presents a dilemma and a gamble to the operative team.

We realize that our actions were a gamble that oxygenation could be maintained. However, it was also clear that pulmonary hemorrhage at the rate described, with no sign of abatement, would prove rapidly fatal. Our later search of the literature confirmed our instincts. Of 8 patients with acute hemorrhage immediately following reinstitution of pulmonary circulation, 7 died. Only our patient and Couves' sole survivor were treated with protamine after discontinuing bypass. Of the 7 fatalities, only 1 patient was taken off bypass and given protamine. In that case, heparinization was apparently reversed by slow titration, and then only after a prolonged period of pulmonary hemorrhage.

On the basis of the outcome of previous cases reported, we recommend the use of protamine as rapidly as extracorporeal circulatory bypass can be abandoned. Since this complication occurs when the pulmonary artery is closed, such action does not compromise the operative procedure. The temptation to remain on bypass should be resisted. Such measures as digitalization, steroids, and diuretics may be of value but do not appear to have had a crucial influence on the outcome.

Although this is a strong position to take on the basis of only 2 survivors out of 9 reported patients, the treatment we recommend is the only one that has, to date, proved successful. Only further experience will show if this course of action is consistently effective.

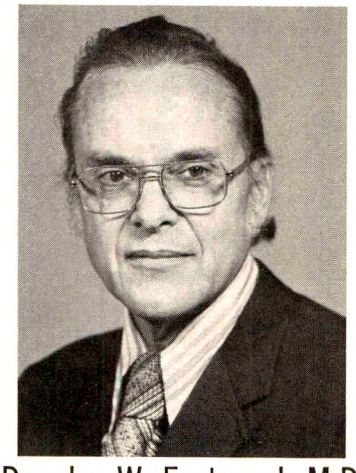
MYOCARDIAL PROTECTION Patients undergoing coronary revascularization are at an increased risk if preinfarction angina and/or ventricular dysfunction (ejection fraction <0.4) are present (high risk patients). Postoperative mortality, infarction and need for inotropic support are greater in these patients as compared with patients without continuous angina or ventricular dysfunction (low risk patients). To reduce the hazard of ischemic injury the following principles of management are recommended: 1) avoid extreme blood pressure changes, 2) monitor left ventricular filling pressure, 3) vent the left ventricle, 4) perform all anastomoses during cardiopulmonary bypass, 5) maintain perfusion pressure >75 Torr, 6) avoid extreme hemodilution, 7) avoid ventricular fibrillation, 8) use intermittent ischemia arrest, 9) repay O_2 debts by prolongation of cardiopulmonary bypass if neccessary. Employing these principles, the need for inotropic support, postoperative infarction and mortality were similar in high and low risk patients. *(Olinger GN, Po J, Maloney JV et al: Coronary revascularization in high versus low risk patients. The role of myocardial protection. Ann Surg 182:293-300, 1975)*

We Salute . . .



Douglas W. Eastwood, M.D.

DOUGLAS W. EASTWOOD can be described in many terms—intelligent, innovative, pragmatic, indefatigable. Those who have worked with him know him also as a superb clinician and teacher.

Doug Eastwood was born the son of a minister in Ellsworth, Wisconsin, in 1918. Moving to Iowa, Doug completed his premedical education at Coe College and subsequently attended and graduated from the University of Iowa College of Medicine in 1943. After a year's residency in Internal Medicine at Detroit Receiving Hospital, he entered the United States Army and served in the European theater. On his return, he entered a residency in anesthesia at the University of Iowa under the direction of Dr. Stuart Cullen. He continued his medical education following completion of his residency, receiving a Master of Science in Pharmacology from the Graduate College of Iowa, after which he served as Instructor and Associate in the Department of Anesthesia.

Doug's clinical and teaching objectives soon crystallized, and in 1950 he accepted a position as Chief of the Division of Anesthesiology at Washington University, St. Louis. Four years later, Doug returned to the University of Iowa as Associate Professor, and in 1955 was appointed Chairman of the Department of Anesthesiology at the University of Virginia Medical Center, Charlottesville.

During the next 15 years in Charlottesville, Doug labored to develop a fledgling department into one that enjoys a national reputation as a training center. Many of his former residents continued in academic positions, to further Doug's clinical and research concepts. His greatest strength has always been the clinical classroom—the operating theater. His technical skill and superb judgment in a clinical setting are widely recognized and readily appreciated by his colleagues. As an innovator, Doug worked on the early development of ventilators and pulse monitors. The first use

of Computer-Assisted Instruction at the University of Virginia Medical Center was implemented by Doug Eastwood and supported by the Department of Anesthesiology.

His constant concern for improvement of teaching technics stimulated Doug to relinquish his Chairmanship to take a year's leave of absence to seek further training in learning methodology. Toward this goal, he was appointed to the Lister Hill National Center for Biomedical Communication of the National Library of Medicine. During that period, he investigated the role of the academic community in the application of educational technology.

In 1972, he joined the faculty at Case Western Reserve Medical Center as Professor of Anesthesiology, with a joint appointment in the Division of Research in Medical Education. In these, his current positions, he is devoting most of his time to graduate medical education while yet maintaining close contact with clinical teaching in the operating room.

Dr. Eastwood is a member of professional and scholarly societies which include Sigma Xi, the American Society of Anesthesiologists, the International Anesthesia Research Society, and the Association of University Anesthetists. He is a diplomate of the American Board of Anesthesiology and a Fellow of the American College of Anesthesiologists. His professional activities include many years of service to the ASA and particularly to the College. He has served as Chairman and Vice-Chairman of the ASA Annual Meetings, and as Chairman of the College Education Resources and Written Examination Committees. He has recently been nominated as President-Elect of the College.

Since 1968, Doug has been an Associate Editor of *Survey of Anesthesiology*. His concern for education has carried him as a consultant to Tanzania for both the World Bank and the United Nations, to evaluate and make recommendations for the expansion of medical education in that country. His numerous scientific publications have been widely recognized, particularly his scholarly work on nitrous oxide.

Doug and his lovely wife, Ruth, have four children and reside in Cleveland Heights, Ohio.

It is with pleasure that we salute our colleague for his many talents and achievements in medicine and anesthesia.

PHENYLEPHRINE-NITROGLYCERIN The effects of combined intravenous nitroglycerin and phenylephrine therapy on the sum of ST segment elevation (ΣST) was determined in 10 patients following acute myocardial infarction. Nitroglycerin reduced mean arterial pressure 22 Torr and left ventricular filling pressure 8 Torr. ΣST decreased 17 mm at the time of maximum hemodynamic effect. Addition of phenylephrine to return the blood pressure to control levels also returned left ventricular filling pressure and ST segment elevation to near pre-nitroglycerin values. The reversal of the beneficial effects of nitroglycerin by phenylephrine suggests a major benefit of nitroglycerin is due to a reduction in left ventricular afterload. *(Come PC, Flaherty JT, Baird MG et al: Reversal by phenylephrine of the bacterial effects of intravenous nitroglycerin in patients with acute myocardial infarction. NEJM 293: 1003-1012, 1975)*

Bacteriologic Aspects of Epidural Analgesia

FRANCIS M. JAMES, III, MD*
RICHARD H. GEORGE, MB, ChB, MRCPath†
HAMID NAIEM, MB, BS, MRCOG‡
GARY J. WHITE, FIMLT§

The incidence of contamination of catheters and syringes used during epidural analgesia for parturients and the effectiveness of bacterial filters were investigated. The effect of bupivacaine on bacterial viability and growth was also studied. Syringes in 5/101 cases were contaminated, while catheter tips located in the epidural space were sterile. Organisms isolated were skin commensals and probably originated on the hands of anesthetic personnel. Bupivacaine (0.25%) was bacteriocidal to *S epidermidis* and *Corynebacterium* spp at 37 C but not at room temperature. These findings illustrate the efficacy of using bacterial filters during continuous epidural analgesia. New syringes should be used for each epidural injection as insurance against seeding of bacteria in the presence of a defective filter.

EPIDURAL analgesia is used in general surgery, obstetrics, peripheral vascular disease, and pain management. Prolonged or intermittent analgesia is achieved by placing a plastic catheter in the epidural space. Attending physicians concerned about the danger of infection from prolonged presence of catheters have questioned the practice of continuous epidural analgesia. Past studies have demonstrated that intravenous cannulae, central venous pressure catheters, and syringes all may be sources of infection.[1-4] In 1962, Barreto[5] found bacterial contamination in 3/35 epidural catheter tips, and Edwards and Hingson[6] reported an epidural abscess following caudal analgesia.

Epidural analgesia is used for approximately 2000 deliveries a year at the Birmingham (England) Maternity Hospital, where it is standard practice to place a bacterial filter* between the hub of the epidural catheter and the local-anesthetic syringe. We investigated the incidence of contamination of syringes and catheters used in epidural analgesia and the effectiveness of the bacterial filter.

*Millex® disposable filter unit, US Pat 3471019, Millipore SA 78 Buc, France.

METHODS

Syringes and epidural catheters used for analgesia during labor in 101 subjects were examined. All catheters were placed in the lumbar epidural space, using careful sterile technic. Anesthesiologists washed their hands and donned plastic apron, cap, mask, and sterile gloves prior to beginning the procedure. The patient's back was cleansed carefully with 2.5% iodine solution and draped in sterile fashion. After identification of the epidural space, a polyvinylchloride catheter was advanced 5 to 10 cm past the epidural needle tip and the needle removed.

The skin was sprayed with plastic dressing, sterile gauze sponges were placed about the catheter, and both sponges and catheter were covered with plastic adhesive tape.

*Associate Professor of Anesthesia, Department of Anesthesia, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, North Carolina 27103.

†Consultant, Department of Bacteriology, Birmingham Maternity Hospital, Birmingham, England.

‡Research Fellow, Department of Anaesthetics, Birmingham Maternity Hospital.

§Chief Technician, Department of Bacteriology, Birmingham Maternity Hospital.

Paper received: 7/28/75
Accepted for publication: 8/13/75

Next, a bacterial 0.22 μm filter through which all local anesthetic solutions were injected was connected to the hub of the epidural catheter. Following a 2-ml test dose of 0.5% lidocaine hydrochloride, analgesia was established with intermittent 8 to 12 ml doses of 0.25 to 0.5% bupivacaine hydrochloride.

At the Birmingham Maternity Hospital, the same 10-ml plastic syringe is often used for local anesthetic administration throughout labor and delivery. We did not attempt to influence whether or not syringes were changed, but the original syringe was marked for subsequent identification. All syringes cultured had been used at least once. After delivery, syringes and catheters were examined for bacterial contamination. Syringes were cultured by aspirating 10 ml of nutrient broth through a sterile 21-gauge needle from a sterile universal container. The broth was drawn 1 - 2 ml past the 10 ml mark on the syringe, gently swirled about, and reinjected into the sterile container.

We attempted to prevent contamination of epidural catheters during removal from the patient's back. After removing the plastic tape and gauze sponge dressing, the skin about the epidural catheter was cleansed with 70% alcohol and allowed to dry. Sterile gloves were worn while withdrawing the catheter, one hand holding the catheter at its point of entry into the skin, the other grasping the distal portion as it was withdrawn from the back. We cut the catheter into two portions, placing each segment in a separate sterile container.

The first 2-cm section of catheter was not cultured, to decrease the chance of isolating bacteria from the skin entry site. The next 4 to 6-cm segment was labeled "A." The distal 4 to 6 cm, "B," represented the catheter tip, which had been located primarily in the epidural space. In the laboratory, 10 ml of nutrient broth were added to the catheter samples, which were then shaken mechanically for 10 minutes to suspend the bacteria. Syringe and catheter specimens were cultured to isolate and enumerate bacterial contaminants. A loopful of broth from all samples was cultured at 37 C on 5% horse-blood agar and MacConkey agar (Lab M), under aerobic conditions, and 5% blood agar anaerobically with 5% added carbon dioxide.

Further samples were cultured at room temperature on blood agar and MacConkey agar. A 1-ml sample was withdrawn aseptically from each container, mixed with molten cooled agar (oxide blood agar base #2) and a pour plate made. Additional pour plates were made from broth diluted 10^{-1} and 10^{-2}. All plates were incubated for 48 hours. If heavy growth occurred in the pour plates, the residual broth, which had been refrigerated overnight, was serially diluted tenfold to 10^{-5} and further pour plates made to determine the viable count. The remainder of the broth from samples showing no growth was incubated for 48 hours to detect low levels of contamination.

Gram-positive cocci which fermented glucose and produced catalase but not coagulase or deoxyribonuclease were classified as *Staphylococcus epidermidis,* and nonmotile, nonsporing gram-positive bacilli which grew on tellurite medium, fermented glucose, produced catalase but not oxidase, and were not acid fast, were classified as *Corynebacterium* species.

Finally, we determined the ability of bacterial isolates to survive in 0.25% bupivacaine at 37 C and room temperature. Broth cultures of the organisms in the stationary phase were centrifuged and washed 3 times in warm saline solution, then suspended in warm saline to approximately 10^{-6} organisms/ml and 0.025 ml of the suspension was added to 5 ml of bupivacaine solution at the appropriate temperature. After mixing, a sample was immediately withdrawn, serially diluted tenfold, and pour plates made. The mixture was sampled in the same way after 3, 5, and 24 hours.

RESULTS

In 67/101 cases, the same syringe was used for all epidural injections, while in 34/101 it was changed at least once. Five syringe cultures were positive, 3 in original syringes and 2 in syringes changed at least once during the analgesic period. Contamination of 2 of these was detected only by incubating the original broth, but on 3 occasions, the total number of viable organisms was very high (table 1) and heavy growth occurred on the related plates. The total number of viable bacteria was deduced by increasing the viable count per milliliter tenfold. The organisms involved, recognized skin commensals, are listed in table 1.

A mean of 4.6 epidural injections were given in the 5 cases where syringes were later noted to be contaminated. This figure was 4.7 for the entire series of 101 patients. One catheter segment "A" was positive for

TABLE 1
Positive Culture Results of Syringes and Catheters

Syringes

Patient	Original syringe	Epidural injections	Organism identity	Viable count
32	No	12	*S epidermidis*	5×10^5
68	No	4	*S epidermidis*	< 9
71	Yes	2	*S epidermidis*	< 9
94	Yes	3	*S epidermidis*	2.5×10^6
99	Yes	4	*Corynebacterium spp*	2.5×10^6
			Catheter (segment A)	
62	Yes	4	*S epidermidis*	< 10

less than 10 *S epidermidis* organisms. This patient (#62, table 1) received 4 epidural injections with the original syringe. Both the syringe and catheter segment B used in this patient were sterile. All other catheter specimens were sterile. The average epidural indwelling catheter time was 18¾ hours.

Alterations in the viable count of the isolates from patients 32, 94, and 99, when incubated at room temperature and at 37 C in 0.25% bupivacaine, are shown in table 2. Bupivacaine was bactericidal to all 3 isolates at 37 C, causing a five-fold and 25-fold decrease in the count, respectively, within 5 hours. At room temperature, the count in 2 strains apparently increased within the first 3 hours but subsequently fell. However, the bacteria still persisted in large numbers.

DISCUSSION

Bacterial filters of 0.22 μm mesh are capable of preventing passage of bacteria even in the presence of heavy contamination. We did not study a control group without bacterial filters, believing this to be unethical since the use of such filters is standard practice at the Birmingham Maternity Hospital. The bacteria cultured from 5/101 syringes used to inject local anesthetic are skin commensals, probably originating from the hands of injecting personnel. On 3 occasions, the level of contamination was surprisingly high. All broth used to sample syringes had previously been checked for sterility. However, multiplication may have occurred during the handling process and in early stages of refrigeration, raising the original count.

Blogg's group[4] showed that at least 50% of plastic and 100% of glass syringes can be contaminated when used more than once. In studying 50 such syringes from an intensive care unit, they noted a 10% incidence of syringe contamination, while the figure for syringes used similarly in operating rooms was 6%. Our 5% incidence is close to this figure and might be explained by the more careful aseptic technic generally employed in operating room and labor areas.

We have not demonstrated that syringes used once are less likely to be contaminated than those used multiple times, but rather that once used, the incidence of syringe contamination is significantly high enough (5%) to warrant using a fresh sterile syringe for each injection. In our series, original syringes were reused throughout the period of epidural analgesia in two thirds of cases. This is common practice in many labor and operating suites, but we feel it should be abandoned for continuous epidural analgesia.

In a study showing bacterial contamination of 3/35 epidural catheter tips, Barreto[5]

TABLE 2
Alterations in Viable Count of Bacterial Isolates Cultured in 0.25% Bupivacaine HCl

	Isolate*	0 hours	3 hours	5 hours	24 hours
Room temperature	Pt #32	1.7×10^6	4.4×10^6	1.1×10^6	1.5×10^5
	94	5.6×10^6	5.76×10^6	4.25×10^6	1.2×10^5
	99	1.02×10^6	2.7×10^6	8×10^5	1×10^5
37 C	32	1.6×10^6	1.4×10^6	1.52×10^5	0
	94	5.25×10^6	2.7×10^6	2×10^5	0
	99	1×10^6	1.6×10^6	2×10^5	0

*Syringes 32 and 94, *S epidermidis*; 99 *Corynebacterium spp.*

assumed in 2 cases that since the organisms were skin flora, they resulted from seeding of the catheters at the site of entry during withdrawal. In the third case, after the dressings were removed the catheter was found lying on skin outside the epidural space.

In our studies, we cleansed the entry site with 70% alcohol before catheter removal, to reduce potential contaminants, discarding the first 2 cm of catheter, as described. In patient #62 (table 1), segment "A" was probably contaminated at the culture site during catheter withdrawal, while segment "B" and the syringe were negative. This suggests the possibility that positive catheter tips in Barreto's study resulted from skin contamination on withdrawal, but the bacteria may also have originated in contaminated syringes, since Barreto did not mention using bacterial filters nor does he discuss the degree of catheter contamination. In the absence of a filter, the number of contaminating bacteria is obviously of importance, as large inocula are more likely to produce infection.

Whether the increased bacterial count in bupivacaine at room temperature represents division into small cell types or active multiplication is as yet uncertain; further studies now in progress will be reported later. In practice, bacteria within the syringe would not be in contact with anesthetic solution for long, as the syringe is emptied completely immediately after refilling, only a small amount of fluid remaining within the nozzle.

The bactericidal effect of bupivacaine at body temperature is reassuring, for it would help to maintain catheter sterility. Procaine hydrochloride and lidocaine have also been shown to possess antimicrobial activity.[7] However, once bacteria succeed in reaching the epidural space, local anesthetics may actually compromise defense mechanisms; Cullen and Haschke[8] demonstrated *in vitro* that lidocaine has a toxic effect on human leukocytes, significantly inhibiting phagocytosis and metabolism. The toxic effect occurs at a concentration of anesthetic lower than that causing antimicrobial activity.

Recently, attention has been called to the possibility of injecting glass particles into patients after aspirating solutions from ampules.[9,10] As bupivacaine for epidural analgesia is supplied in glass ampules, bacterial filters provide an additional advantage by diminishing the danger of injecting glass particles into the epidural space.

Our findings concur with those of Blogg's group[4] in demonstrating the problem of contamination when syringes are used more than once. Although we have not proved that catheter contamination would have occurred in the presence of contaminated syringes if microfilters were not used, the finding of a 5% rate of syringe contamination should encourage the practice of placing an effective bacterial filter between injecting syringes and epidural catheters.

We recommend that bacterial filters be used in all cases of continuous epidural or continuous spinal analgesia. Since a filter may be defective, we recommend that syringes should be changed between each epidural injection. If these precautions are used and careful aseptic technic is followed in initial catheter placement, there is little chance of bacterial contamination of the epidural space.

Resection of Stenotic Trachea: A Case Presentation

C. PAUL BOYAN, M.D.*
PAUL A. PRIVITERA, CRNA†
Richmond, Virginia‡

Tracheal stenosis is usually a complication of prolonged mechanical ventilation. If the narrowing is severe it will greatly obstruct the air flow. Resection of the damaged trachea is a life saving procedure. The anesthetic management of the resection of an "ice cream cone narrowing" of the trachea (3 mm diameter) 4 cm above the carina is reported. A forced vital capacity loop (expiration-inspiration) of air flow versus volume revealed preoperatively little difference in the flow during the forced (F-V) and resting ventilation (Vt), thus confirming a diagnosis of severe upper airway obstruction. A total obstruction of the air flow was encountered during the skeletonization of the trachea and the surgeon was allowed to work for not more than 60 seconds at a time. Perfect cooperation between the surgeon and the anesthesia team is necessary for the successful completion of this type of surgery.

STENOSIS of the trachea is seen most often, and is usually due to long-lasting mechanical ventilation, in intensive-therapy patients requiring tracheostomy or prolonged endotracheal intubation. The following case describes the management of anesthesia for resection of a large segment of a stenotic trachea.

CASE REPORT

A 46-year-old obese (94.8 kg) Caucasian man was admitted on 9/24/73 to the hospital with a diagnosis of acute respiratory and congestive heart failure. Past medical history showed chronic bronchitis, emphysema, repeated lung infections, diabetes mellitus (controlled by diet), myocardial infarct (1970), and polycythemia. In spite of nasal O_2 and drug treatment, his situation deteriorated. At this time, blood gases were Pao_2 36 torr, Sao_2 65%, $Paco_2$ >100 torr, pH 7.34, base excess >+16, and HCO_3^- >50. He was intubated and ventilated mechanically for 7 days. With intensive treatment, he gradually recovered and was discharged improved after 18 days of hospitalization.

One month after the prolonged endotracheal intubation, he was readmitted with audible stridor and pronounced dyspnea at rest, unable to breathe adequately even with increased inspiratory and expiratory efforts, and "tugged for breath." Therapy with aminophylline, meperidine, and O_2 by nasal cannula produced slight relief. Tomograms of the trachea demonstrated a tapered 5 cm narrowing of the trachea, 4 cm of normal trachea present between the lower end of the structure and the carina. Bronchoscopy under local anesthesia showed "ice cream cone" narrowing of the trachea beginning 8 cm below the vocal cords.

Four hours after bronchoscopy, the patient developed respiratory difficulty. Blood gases were Pao_2 80 torr, Sao_2 88%, pH 7.07, $Paco_2$ 88 torr, HCO_3^- 24. With proper treatment, the patient recovered, although still having difficulty moving air in and out.

A forced vital capacity loop (expiration-inspiration) of air flow versus volume revealed little difference in the flow during forced (F-V) and resting ventilation (Vt), confirming the diagnosis of fixed upper-airway obstruction (fig 1). Resection of the stenotic trachea with primary anastomosis was proposed.

On the day of operation, the patient was premedicated with 50 mg of diphenhydramine HCl and 0.8 mg of atropine. The surgeons and the anesthesia team agreed to constant communication throughout the operation. The patient was preoxygenated with 100% O_2 for several minutes and then induced with 300 mg of sodium thiopental. Succinylcholine (100 mg) provided sufficient muscle relation for uneventful intubation with a plastic 9 mm cuffed endotracheal tube, placed above the constriction (fig 2). Tidal exchange of 800 ml was achieved with 30 torr normal pressure over 4 to 5 seconds and the expiratory phase was the same. Anesthesia was maintained with halothane 0.5 to 1.5%, with supplemental doses of d-tubocurarine and morphine. Midline sternal incision provided good access to the trachea.

Surgical retraction and manipulation to free the trachea from adhesions caused total obstruction of ventilation; therefore, after several inflations of the lung with 100% O_2, the surgeon was allowed to work for not more than 60 seconds. Lungs were ventilated again with 100% O_2, followed by more operative procedure. This pattern of ventilation and occlusion was maintained for 20 minutes. At times it was necessary to increase positive pressure in the breathing bag to as high as 60 torr to secure sufficient tidal volume. After the lower part of the trachea was freed, the distal normal section was severed, and a sterile wire-spiral cuffed tube attached to sterile corrugated tubing was introduced into the tracheal stump by the surgeon. The balloon was inflated and the semiclosed system was reestablished (fig 3). The original orotracheal tube was pulled up above the upper end of the tracheal stenosis. After the stenotic area (circa 5 cm) was resected and the posterior healthy parts of the trachea were approximated with nylon stitches, the original endotracheal tube was pushed down and replaced the outside tube, introduced by the surgeon, in the lower end of the trachea above the bifurcation (fig 4).

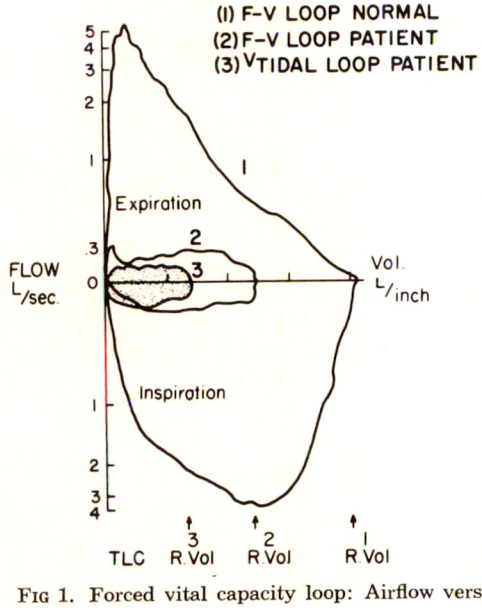

FIG 1. Forced vital capacity loop: Airflow versus volume.

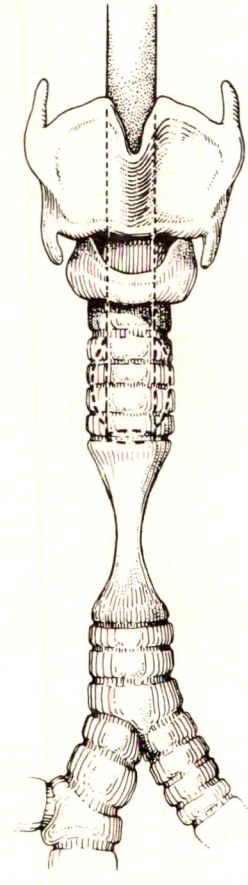

FIG 2. Intubation to stenotic portion of trachea.

The end-to-end anastomosis was completed around the endotracheal tube and required extreme flexion of the head. The

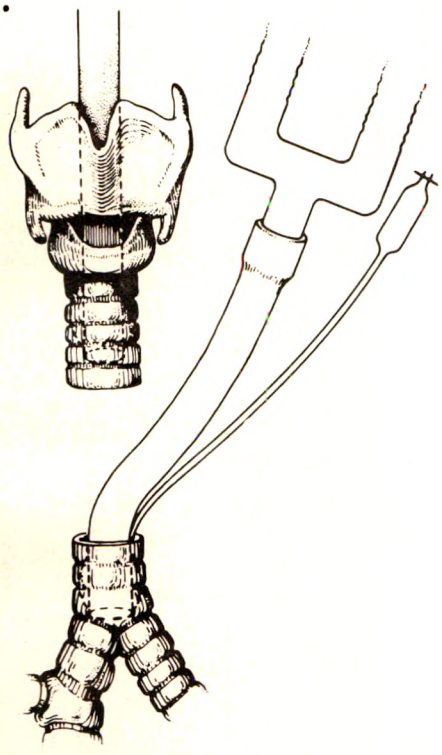

FIG 3. Resection of stenotic trachea.

operation lasted 6 hours. The pathologic specimen was 4.5 cm long and showed a cylindrical stenosis of 3 mm in diameter (fig 5).

The patient was maintained on a ventilator with endotracheal tube for 24 hours. On the 2nd postoperative day, blood gases while the patient was receiving O_2 (3 L) via nasal cannula were Pao_2 66 torr, Sao_2 92%, $Paco_2$ 47 torr, pH 7.38, HCO_3^- 26.9. Postoperatively, the patient developed some atelectasis and pleural effusion at the left lung base. He was discharged much improved on the 21st postoperative day. A 24-month follow-up found him well recovered and working full time at his gasoline station.

DISCUSSION

Tracheal stenosis as a complication of prolonged intubation and mechanical ventilation is a crippling disease which restricts physical activities. Any additional tracheobronchial infection will dangerously aggravate the existing situation. Such narrowing of the trachea (3 mm) as in this patient imposes severe obstruction to the air flow. The forced vital capacity flow-volume loop (fig 1) showed a great reduction in the initial flow of exhalation as compared to normal (0.3 L/sec to 5.5 L/sec). This flow was maintained throughout the entire phase at the same reduced level, demonstrating a constant obstruction by the stenotic area. The same was true for the inhalation phase.

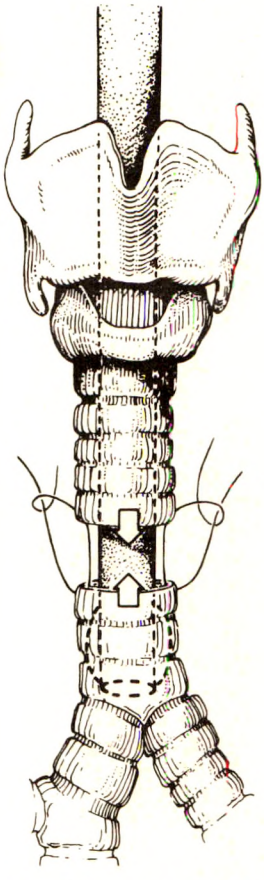

FIG 4. Postresection anastomosis of trachea, with intubation.

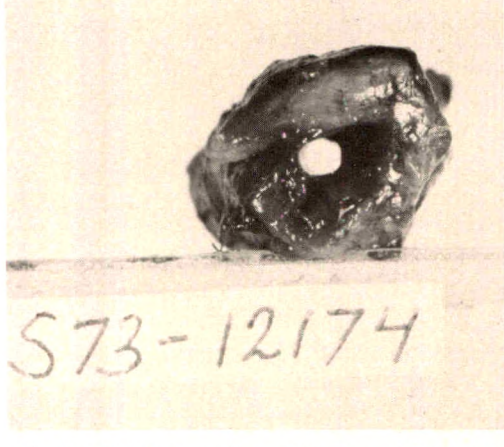

FIG 5. Histologic section of trachea (4.5 cm with 3 mm passage).

Peak flow was greatly reduced but was maintained at the same level throughout exhalation, thus confirming the existence of constant obstruction to the air flow. Miller and Hyatt[1] have suggested that the flow-volume plot of a forced expiratory and inspiratory vital capacity maneuver may be helpful in detecting airway obstructions. Patients having such a tracheal obstruction breathe slowly because they cannot rapidly increase their tidal volume despite additional muscular efforts.

The resting Vt-loop in this patient showed the same restriction in peak flow in both phases with sustained flow throughout the inhalation-exhalation cycle. This type of ventilation requires additional and constant muscular efforts, leading to dyspnea even at rest. The slightest edema of the tracheal mucosa will have similar effects on the air flow by further decreasing the diameter of the obstruction.

In this patient, perfect cooperation between the surgical and anesthesia teams was achieved. The dangerous points during the anesthetic management were complete obstruction during the dissection of the trachea and concern if such an obstruction cannot be relieved by eliminating retraction or any other pressure on the trachea. If the last situation were to occur, the trachea below the obstruction, although not properly dissected, should be opened and a sterile endotracheal tube inserted by the surgeon. Even though this is not the best approach to preserve as much as possible of normal trachea, it is lifesaving.

We were able to ventilate our patient at intervals during the dangerous period of dissecting the trachea and the surgeon desisted from manipulation at the end of 60 seconds, as agreed upon, thus relieving the obstruction. Postoperative care was complicated by having extreme head flexion to reduce the tension at the suture line due to resection of a large segment of the trachea.

In this patient, the endotracheal intubation causing the severe tracheal stenosis had lasted for 7 days, and it took less than a month to develop this life-threatening respiratory complication.

Similar anesthetic technics have been reported by others.[2-5]

Factors Influencing Choice Between Tracheostomy and Prolonged Translaryngeal Intubation in Acute Respiratory Failure: A Prospective Study

MOUSTAFA EL-NAGGAR, MD*
SESHADRI SADAGOPAN, MD†
HARRY LEVINE, PhD‡
HARVEY KANTOR, MD§
VINCENT J. COLLINS, MD‖
Chicago, Illinois**

One of the problems of prolonged ventilatory therapy in acute respiratory failure (ARF) is the need to choose between tracheostomy after 48 to 72 hours of translaryngeal (TL) tracheal intubation or the continuous use of the TL tube for a period of 10 days. Too often the choice has been based on retrospective studies or personal preference. To investigate this problem prospectively, 52 adults in ARF were divided sequentially into 2 groups on their 3rd day of TL intubation. Patients in group I (G-I) retained the TL tube for a total of 11 days; those in group II (G-II) were tracheostomized on the 3rd day. The following factors were used to evaluate the efficiency and complications in each group: patient's epidemiologic variables, daily pulmonary functions, severity of respiratory infections, and scores of post-intubation airway lesions.

No consistent statistically significant differences between the two procedures were seen in the pulmonary functions or the range of individual patient variables. However, with an early tracheostomy, there was an eightfold greater incidence of contamination of the airway by new organisms, airway lesions were more frequent and severe, and the need for the tracheal tube was extended.

To identify the epidemiologic variables and the pulmonary functions that discriminate between patients with serious airway lesions and those with mild lesions, and to evaluate the ability of these variables to differentiate the patients who died from those who survived, the distribution of all factors was compared in the two categories. The epidemiologic variables separated the patients according to their airway lesions only, while the difference in pulmonary functions was statistically significant only between the patients who died and those who survived.

DURING the past decade, there has been a dramatic change in the type of tracheal tubes used in the management of patients in acute respiratory failure (ARF).[1] In the early sixties, it was realized that an initial tracheostomy was justifiable only when translaryngeal (TL) intubation of the trachea was not possible.[2] It was then common practice to perform the tracheostomy within the following 24 hours, if the need for the tracheal tube continued.[3]

In the late sixties, interest increased in prolonging the period of TL intubation, because of dissatisfaction with the results of tracheostomy in some patients.[4] The complications of transtracheal (TT) intubation,

fairly frequent and often serious,[5] included bleeding, difficulty in cannulation, dislodgement, generalized surgical emphysema, pneumothorax, tracheal stricture and fistulas, and scar formation. With improvements in construction of tracheal tubes and in the overall management of patients with an artificial airway,[6] clinicians prolonged the duration of TL endotracheal intubation.[7] This practice was also accompanied by complications, such as mucus obstruction, accidental extubation, pneumonia, ulceration of nostrils or nasal septum, hoarseness, cord avulsion-perforation, dislodgement of the tube into the right main bronchus, and tracheal stenosis.

Currently there is no agreement as to the optimum period of TL intubation after which tracheostomy is indicated. Even Lindholm, in an extensive study of prolonged tracheal intubation, affirmed that he could not establish a time limit.[8] Pontoppidan's group[1] retained TL tubes up to 8 days, while Safar[9] recommended tracheostomy on the 3rd day of TL intubation.

The present study was undertaken to compare the efficacy and safety of prolonged TL and TT intubation in adults in ARF and to identify factors that may influence the outcome of therapy.

METHODS AND MATERIALS

On their 3rd day of TL intubation, 52 adult patients in ARF who were judged to require continued intubation for a further period of time were sequentially divided into 2 groups. Patients in group I (G-I) were managed by continued TL airway for a total period of 10 to 11 days, after which tracheostomy was to be performed, if the need for an artificial airway continued. Patients in group II (G-II) were to be tracheostomized on the 3rd day of artificial airway care.* All 52 patients received the same respiratory, general, and supportive care, according to individual needs and the policies and procedures of the general intensive care unit.

Criteria for scoring respiratory infections included vital signs, laboratory findings, and x-rays (table 1). After extubation, patients were examined by a member of the ENT staff, using a Macintosh-blade laryngoscope and a fiberoptic bronchoscope. Pharyngeal, laryngeal, and tracheal lesions were rated according to modified Lindholm scoring system.[8] Epidemiologic variables and respiratory measurements (table 2) were collected daily on computer-coded forms by the second author, who was not in charge of patient care during the study.† Some of the data collected were deleted because of incomplete information, inadequacy of method of determination, or difficulty in statistical interpretation. The Fisher linear discriminant function test was used to quantitate the distribution of the epidemiologic variables in the following groups of patients: (a) patients who had prolonged TL intubation versus those who had an early tracheostomy; (b) patients who had mild airway lesions versus those who had serious lesions; and (c) patients who were extubated versus those who died.

discriminant analysis test yielded an f $(16.35) = 1.31$; p value > 0.25. This indicated that the epidemiologic variables were equally distributed between the TL and TT groups. The type and frequency of organisms newly identified in daily examined tracheal aspirate was similar during the first 4 days of management G-I and G-II. However, between the 4th to 11th days, there was an 8-fold increase in the number of newly identified organisms in G-II in comparison to G-I (table 3).

The mean score for airway lesions/day of management (fig 1) was significantly higher in G-II than in G-I ($p < 0.05$). The 26 patients in G-II had an average score of 1 for the lesions evaluated when these patients were tracheostomized on the 3rd day of TL intubation. This same score in G-I was observed on the 7th and 8th days. Because the patients in G-II were managed by two types of tubes, the average score on the 3rd day was added to that on subsequent days (fig 1). The combined scores of airway lesions in G-II were also significantly higher ($p < 0.01$) than in G-I.

In a comparison of the percentages of the cumulative number of patients extubated or expired and the number of patients being treated in G-I or G-II at the specific day of management (fig 2), analysis of variance test showed the difference in these percentages between the expired patients in G-I and G-II were statistically insignificant,

TABLE 3

while the higher percentages in the extubated patients in G-I were statistically more significant than those in G-II. These results indicated a significant delay in extubating the tracheostomized patients (G-II), independent of the outcome or duration of therapy.

There were sporadic and inconsistent differences in the means and SD of the respiratory measurements according to day of management. In G-II, with the exception of V_D/V_T ratio determination, there was a significant deterioration in these measured values subsequent to the tracheostomy on the 4th day of management.

Indecisive Variables Include

1. Initial diagnosis (medical or surgical)
2. Alcohol intake
3. Habituation to narcotics
4. Respiratory rate >35 as indication for intubation
5. Free airway as indication for intubation
6. Duration of TT intubation
7. Number of attempts to intubate trachea translaryngeally

that 15 of 22 variables (table 4) correctly classified 46 patients out of 52 into group A and incorrectly classified 6 patients with mild lesions. The test yielded an $f = 4.33$, with 13 and 38 degrees of freedom, and a p value of <0.001.

There was no significant difference between the mean values of the 6 respiratory parameters (RI, $P_{(A-a)}$ O_2 (100%), V_D/V_T, TV, FVC, or EDC) per day of management or the number or type of positive bacteriologic cultures in the patients who had mild or serious airway lesions.

There was no correlation between the airway lesions at the cuff site and the following factors: (a) duration of intubation; (b) type of tracheal tube; (c) extubation or death; and (d) epidemiologic variables or respiratory measurements.

C. Variables that Influence the Prognosis of Prolonged Tracheal Intubation (death during the study versus extubation).—The 52 patients included in the study were categorized as follows: (1) those who died during the study; (2) those successfully extubated and discharged from the General Intensive Care Unit (GICU). The linear discriminant function test, used to investigate the distribution of the epidemiologic variables between those two categories, yielded an $f\ (16.35) = 0.75$ with 16 and 35 degrees of freedom ($p<0.10$), indicating that the epidemiologic variables could not help predict which patients would die and which would be extubated.

Although there was no significant difference in respiratory measurements on the 1st day of management, in subsequent days significant and consistent differences were observed in the following measured values, in the following order: TV and FVC on the 2nd day, RI on the 3rd day and $P_{(A-a)}$ O_2 (100%) and EDC on the 5th day. The mean values of the V_D/V_T x 100, however, showed no significant difference between the group of patients who died and the group subsequently extubated.

In the expired group, the percent incidence of identified organisms was double that in the extubated patient group, while the prevalence of *E coli, Pseudomonas* species, *Klebsiellae, Hemophilus influenzae,* and *S aureus* was almost 3 times greater.

Mean values of respiratory measurements in the extubated group and expired group on the 1st and last days of management are shown in table 5.

DISCUSSION

In the past, prolonged therapeutic tracheal intubation has been defined as the maintenance of an artificial airway for more than a few hours.[10] This definition is unsatisfactory, due to the common use of intubation in the management of ARF for longer periods.[1,3,9] We chose the period of 3 days to define prolonged intubation, because TL tubes are commonly used in the initial 48 to 72 hours of artificial airway care, while there is no agreement regarding the choice between TL and TT intubation beyond this period.

Advocates of TT intubation on the 3rd day of management claim better removal of secretions, reduction of dead space, and better tolerance by patients.[8] Advantages

TABLE 5
Means and Standard Deviations of Values on 1st Day of Management and Day of Extubation or Death

	Patients survived		Patients died	
	Means and (SD) on 1st day	Means and (SD) on day of extubation	Means and (SD) on 1st day	Means and (SD) on day of death
Number of observations	30		22	
Tidal volume (TV/ml)	269 (117)	409 (105)	213 (101)	188 (34.7)
Forced vital capacity (FVC/ml)	753 (358)	1227 (399)	42 (214)	728 (233)
Effective dynamic compl (EDC/ml/cm H_2O)	21 (6)	36 (8.5)	22 (7.4)	22 (8.8)
V_D/V_T ratio	49 (11.4)	38 (10.3)	50 (10.5)	49 (6.3)
$\triangle P_{(A-a)} O_2$ (100%)	397 (105)	244 (68)	391 (98)	423 (84)
Respiratory infections (RI)	4.3 (2.3)	2.16 (1.9)	4.9 (3)	9 (3.9)

1. There was no significant difference in the 2 groups between mean values on 1st day.
2. Differences between mean values on day of extubation or death in G-I and G-II were highly significant.
3. With exception of scores of respiratory infections, differences between mean values on 1st day and day of death were statistically insignificant. There was a highly significant difference between mean values on 1st day and day of extubation (p 0.005 to 0.001)

claimed for TL intubation for over 3 days include better tube stability and tracheal alignment, absence of a surgical wound, and less bacterial invasion.

In this prospective study, the differences in the daily respiratory measurements between prolonged TL intubation and an early tracheostomy were only sporadically significant. This indicated that the TL and TT tubes were equally efficient in the management of ARF. However, the disadvantages in an early tracheostomy include deterioration in post-tracheostomy pulmonary function measurements, which may not be well tolerated by the unstable patient, and an increase in identified pathogens, which may invite the unnecessary administration of antibiotics. There is also a tendency to delay removal of the TT tube, which increases the cost of patient care and prolongs the risks inherent in artificial airways. In addition, airway lesions (excluding those related to the cuff) in early tracheostomized patients not only showed significantly higher scores but also tended to be delayed and of a more serious nature.

One patient had a granuloma at the tracheostomy site at the time of extubation and was discharged from the hospital for outpatient followup. Two weeks later, he was seen in the emergency room, where he sustained cardiopulmonary arrest due to severe tracheal stenosis. Immediate resuscitation was successful; however, the patient did not regain consciousness and later died. Two more patients who had an early tracheostomy also developed tracheal stenosis; one had a resection anastomosis and the other a permanent tracheostomy. Another patient developed a tracheoesophageal fistula at the tip of the TT that was related to misalignment of the tube.

Two women with status epilepticus showed subglottic cicatrical web formation after 3 days of translaryngeal intubation. Both were successfully treated by dilation.

In our view, the major advantage of maintaining the TL tube for 11 days was the fact that only 10 out of 52 patients needed airway care beyond this period. Thus, 80% of the patients in ARF who required a tracheal tube for 3 days or more could have been spared the tracheostomy procedure.

The airway lesions described in this report were less severe or frequent than those reported by Lindholm[11] and by Hedden's group[12] but similar to those observed by Deane and Mills.[13] The latter investigators found fewer complications in patients intubated more than 100 hours. In our study, there was a linear correlation between the duration of intubation and the severity of the lesions observed. For this reason we recommend limiting the period of translaryngeal intubation to 11 days.

Factors common to patients with serious airway lesions (table 4) suggest that it is

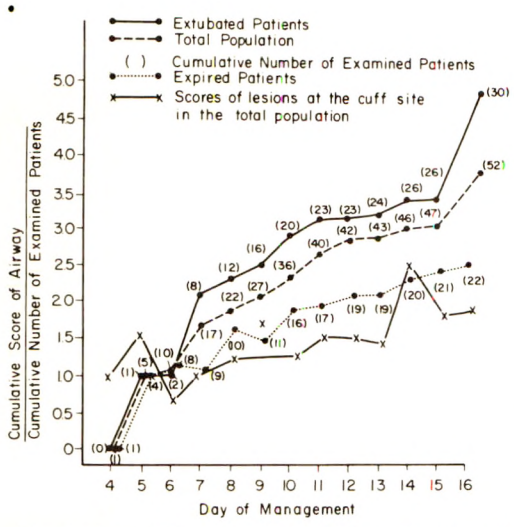

FIG 3. Cumulative scores for lesions per day of management in patients extubated, patients expired, total population of patients examined, and at cuff site.

the degree of friction between the artificial airway and the air passages that is significant. Lesions were more common (1) in patients on spontaneous or assisted ventilation, where friction is unavoidable; (2) in patients who survived (fig 3); and (3) in the 2 patients in status epilepticus. Unexpectedly, there was a correlation between steroid administration and serious airway lesions, but no correlation between these lesions and the number of attempts to intubate the trachea. The latter observation agrees with that by Fassolt.[14]

None of the epidemiologic variables or respiratory measurements (table 2) was useful for predicting the outcome of prolonged tracheal intubation for ARF on the 1st day of management, a favorable prognosis depending on improvement in pulmonary function. A poor prognosis was associated not only with lack of improvement in these measurements but also with an increased score in respiratory infections (table 5).

ACKNOWLEDGMENT

The Physician & The Law

Anesthetic Manufacturer not Liable for Death of Patient

Two physicians and the manufacturer of an anesthetic were not liable for the death of a patient from a cardiac arrest during surgery, a federal appellate court in Ohio ruled.

The patient had been operated on for removal of a cataract in his right eye. Innovar was administered as an anesthetic agent. During the operation, the patient suffered a cardiac arrest and brain damage and died about two weeks later.

Claiming that the manufacturer was negligent in failing to adequately warn users of the drug of its side-effects and adverse reactions, the patient's widow brought an action against the manufacturer. She also brought an action against the ophthalmologist and the anesthesiologist based on their selection of Innovar and their efforts to resuscitate the patient after his cardiac arrest. A jury found in favor of the physicians and the manufacturer, and the widow appealed.

On appeal, she contended that the trial court improperly permitted the physicians and their experts to testify to their experience with Innovar after the operation. The federal appellate court said that the liability of the manufacturer and the physicians could be measured only by their knowledge of the drug obtained prior to the operation. However, no objection to the testimony by the physicians or their experts was made at trial. The federal court said that the factual issues had been fairly presented to the jury and affirmed the trial court's judgment.—*Daly v. Cardiovascular Effects of Cannabinol During Oral Surgery

JOHN M. GREGG, DDS, PhD*

Fifty-five clinical trials were conducted to determine the cardiovascular combined effects of stressful oral surgery and systemic cannabinols. In a first study, $\triangle^9$-tetrahydrocannabinol (THC) was given IV as a premedicant and compared with diazepam and with a placebo. A classic dose-related tachycardia followed THC injection. The peak heart rate response of patients premedicated with 0.044 mg/kg THC was 24.1% higher ($p<0.05$) than the peak effect for a nonsurgerized control group, suggesting a synergistic effect between THC and surgical stress. A predisposition to syncopal hypotension followed THC premedication, and antiarrhythmic effects were observed after large doses. The injection of local anesthetic preparations containing epinephrine did not alter THC cardiovascular response. An apparent drug interaction was observed, however, in a second study, in patients given general anesthesia within 72 hours after smoking marijuana. These patients demonstrated sustained abnormal postoperative tachycardia when compared with control nonsmokers, an effect which may have resulted from an interaction between stored cannabinol metabolites and atropine administered as part of the anesthetic technic. It was concluded that THC had no particular advantage over diazepam or placebo as a premedicant. Further, THC altered the patients' adaptivity to stress and interacted undesirably with other anesthetic medications.

THE cannabinols, the most heavily used psychoactive drugs in the world, are used by an estimated 250,000,000 persons. The 1972 estimates for college-age users was 54% (with about 5 to 10% of these using marijuana on a daily basis), and 1980 projections for young adults have been set at 66%.[1] Inevitably, more marijuana users will be approaching elective or emergency surgical anesthesia after having "premedicated" themselves with cannabinols.

Marijuana has several properties that suggest it might be useful as a surgical premedicant: analgesia in subhumans;[2] antisialosis;[3] a moderate amnesic effect;[4] a low or nonexistent addiction potential;[5] and a very low toxicity.[5] Death from cannabinol overdose has rarely been reported, and most severe reactions have occurred following uncontrolled IV injections. Extrapolating from animal toxicity studies, a human LD_{50} of at least 30 mg/kg is far above the psychologically effective range, and much more favorable than that of alcohol.[5] And finally, the extensive use of marijuana as a social drug suggests a pleasant psychic experience which could also serve well as a surgical pain and anxiety sedative.

There is considerable evidence, however, that significant incompatibilities may exist

between cannabinol premedication and surgical anesthesia, making this drug of questionable value in this situation. Although the response to marijuana, as to most psychoactive drugs, is largely determined by dose[6] and route of administration,[7] personality factors,[8] psychologic set,[9] and especially the stress of the environmental setting[3,10] appear inordinately significant. For example, dysphoric "high" responses ("highs") with marijuana are more commonly seen in patients with chronic depression,[11] and paranoid delusional reactions occur more frequently in hypnotic-suggestible patients.[12] Marijuana is now looked upon as a mood-intensifying drug rather than as a pure CNS excitant, euphoriant, or depressant per se.[13] Thus, it might be anticipated that the psychophysiologic stress of a surgical experience in the marijuana-premedicated patient could result in an exaggerated sympathoadrenal stress response.

Most of the adverse effects reported for marijuana have been on cardiovascular functions and related drug interactions. As in the present study, the most consistently reported pharmacologic response is a dose-related tachycardia.[14,15] Both hypotensive and hypertensive effects have been described.[16,17] The combination of increased cardiac demand from tachycardia with sustained catecholamine elevation has led some authors to warn that the use of cannabinols in elderly or in cardiac patients may be hazardous.[5,15] Studies of patients with angina pectoris support this warning, for it has been shown that smoking marijuana significantly decreases exercise tolerance when compared to placebo smoking.[18]

Studies of long-term hashish users have demonstrated elevated hemoglobin and packed-cell volumes, which have been attributed to chronic hypoxia.[1,19] There are also reports of increased potential for cardiac arrhythmias,[18] and ECG studies have demonstrated shortening of the S-T interval and depression of T-wave amplitude.[20] Other studies, however, have indicated that cannibinols may actually have a therapeutic or protective effect against cardiac arrhythmias.[21] Nevertheless, because the incidence of arrhythmia during oral surgery with local anesthesia alone has been reported as greater than 45%,[22] our investigations of cannabinol effects appear warranted.

There have been other warnings of dangerous drug interactions between marijuana and anesthetic medications. Cannabinols have been shown to double ketamine sleeping time and to quadruple thiopental duration.[23] Pentobarbital sleeping time in rats was doubled after a single cannabinol dose.[24] Marijuana is also known to potentiate the depressant effects of alcohol[25] and to summate with amphetamines.[26] Beaconsfield's group[14] predicted dangerous cardiovascular drug interactions between marijuana and such common agents as atropine or local-anesthetic preparations containing epinephrine.

Our studies were designed to determine the cardiovascular effects of cannabinols (1) by comparing the cardiovascular effects of premedicant IV doses of THC, diazepam, and placebo, and (2) by a retrospective study of the cardiovascular effects of outpatient general anesthesia in patients known to have smoked marijuana within 72 hours before anesthesia.

STUDY 1: METHODS

Ten healthy male patients between 19 and 28 years of age (mean 26 ± 2.8 yr SD) were selected for study, without regard to prior marijuana experience, from a population requiring elective surgical removal of 4 impacted 3rd molars. All 10 subjects had smoked marijuana, and 2 admitted to previous experiences with LSD-25 and mescaline. After explanation of the procedure and the risks involved, informed consent was obtained. A complete physical examination, including ECG, chest x-ray, and laboratory tests, showed all subjects to be healthy and free of cardiovascular or respiratory abnormalities. Each subject participated in 4 separate weekly clinical trials, at which time a single 3rd molar was removed, and during which time he was premedicated with one of the following 4 agents:

1. THC: 0.044 mg/kg* ("larger dose")
2. THC: 0.022 mg/kg* ("smaller dose")
3. Diazepam: 0.157 mg/kg
4. Placebo (dextrose 5%, NaCl): 0.2%

These were given in random order on 4 consecutive weeks, double-blind with respect to patient and surgeon. This allowed each patient to serve as his own control for measuring cardiovascular changes. The THC solutions were prepared by dissolving the

*These 2 dosages were selected from a pilot study in which 0.02 mg/kg was found to consistently produce minimal subjective "highs" and 0.04 mg/kg consistently produced near-100% "highs." Subjects reported that IV "highs" were equal to or beyond the usual effects from smoking marijuana.

dose of active THC in 0.5 ml of ethyl alcohol and adding 25 ml of human serum albumin.

On the morning of each clinical trial, patients, who had fasted since midnight and had recently voided, were brought to the clinical research unit. All had been asked to avoid smoking in any form for at least 24 hours before each clinical trial. Patients reclined in an approximately 30° sitting position throughout the test period. The ECG was continuously recorded from a modified lead II placed entirely on the thoracic cage, and heart rate was monitored electronically from the ECG. Indirect systolic and diastolic blood pressures were recorded at 2-minute intervals with a Litton phonosensor. All transducer signals were preamplified and oscilloscope-displayed through the Litton Product Basic Bedside Unit. Continuous recording of output was made on a 12-channel Honeywell 5600 electromagnetic tape recorder and subsequently printed out on the Siemens Mingograph® polygraph.

Simultaneously with the cardiovascular monitoring, subjective psychologic drug effects were studied, using the State-Trait Anxiety Inventory (STAI),[27] a modified Subjective Drug Effects Questionnaire (SDEQ),[28] and the measure of subjective "high" described by Perez-Reyes and coworkers.[29] Details of these tests are contained in another report.[30]

Baseline resting physiologic functions were monitored for a 30-minute period, and the injection procedure was isolated and shielded from the patient's view. Patients were told that the injection was to begin, and the premedicant was injected evenly over a 5-minute period through an indwelling venous catheter, after which the surgeon and nurse entered the operatory, where they administered the local anesthetic. Appropriate peripheral trigeminal blocks were performed by standard aspiration technic, using an average of 2 to 4 ml (40 to 80 mg) of 2% lidocaine containing 40 to 60 mcg of 1:100,000 epinephrine. The surgeon then removed the molar by ordinary surgical technics, pacing the procedure to be completed exactly 30 minutes after drug injection. Following a 30-minute surgical test period, the patient remained in the operating chair for an additional 60 minutes of monitoring and then was escorted to a recovery room, where monitoring continued for a minimum of 60 minutes until discharge.

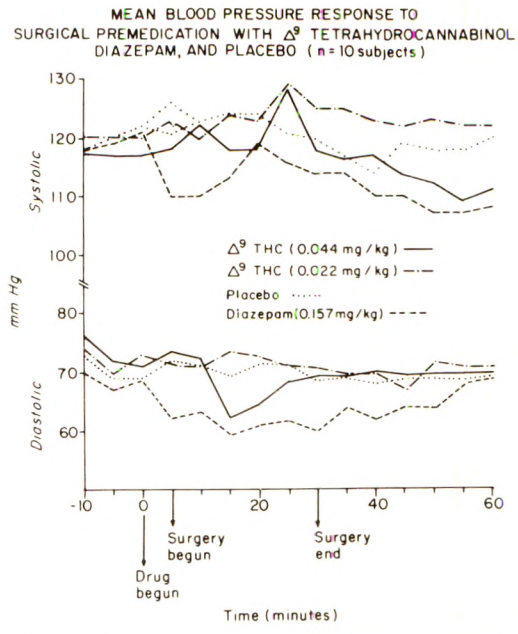

FIG 1. Measures of blood pressure response to surgical premedication with ⁹THC revealed a peak systolic hypertension 25 minutes after injection. A mild gradual hypotensive trend followed the end of surgery with the larger THC dose.

The additional control group of 5 nonsurgerized volunteers consisted of healthy men, aged 21 to 34 (mean 26 ±3.2 SD), who underwent a single trial in which they were given a single dose of THC (0.044 mg/kg) from the batch used in the main experiment described above. Cardiovascular monitoring, subjective measurements, and experimental setting were identical, but no operations were performed. When cardiovascular data from this group were compared with data from the main experiment, influences that could be attributed solely to drug effect could be separated from those due to drug-surgical stress interactions.

STUDY 1: RESULTS

Blood Pressure.—The average blood pressure response to surgical premedication with THC changed little from average preoperative baselines and placebo levels (fig 1). A mild elevation of systolic pressure was observed, with the peak effect at the 25-minute postinjection interval; the larger dose of THC produced an average elevation of 8 torr, and a 9-torr elevation followed the smaller dose. In the larger-dosage THC group, a gradual hypotensive trend was observed, beginning approximately at the time of completion of the operative procedure and reaching an average maximum depression of 12 torr below preoperative baseline

and 14 torr below placebo levels at the 55-minute postinjection time period. Blood pressures following larger doses of THC returned gradually to placebo levels an average of 70 minutes after initial drug injection.

The blood pressure effects of diazepam were dissimilar to those of THC: Diazepam consistently induced a mild systolic hypotension, ranging from 7 to 15 torr throughout the entire trial. However, average diastolic responses to both dosages of THC were statistically and clinically similar to placebo responses throughout.

Transient moderate hypotension of 20 to 45 torr systolic and diastolic in the interval of 4 to 8 minutes after THC injection occurred in 3/10 subjects. These episodes appeared to be typical syncope, associated with nausea, dizziness, anxiety complaints, and, in 2 instances, loss of consciousness accompanied by carpopedal spasm for up to 25 seconds. No similar syncopal responses or transient hypotension was observed with any of the patients given placebo or diazepam.

Blood pressure response in the period during and immediately after administration of the local anesthetic (lidocaine with epinephrine) was not significantly different from placebo responses with either dose of THC or diazepam.

Heart Rate.—Comparison between both dosages of THC, which induced tachycardia in all surgical patients, and response to diazepam and placebo premedicants (fig 2) showed the average peak heart rate increase with 0.044 mg/kg THC to be 69% above preoperative baseline and 36% above placebo peak. The greatest elevation occurred ± 18 minutes after the start of drug injection. Peak heart rate increases after 0.022 mg/kg THC occurred typically at the 15-minute postinjection interval, with 53% above preoperative baseline and 26% above placebo peak. Although heart rate peak time was similar with both doses of THC, the duration of tachycardia differed. Whereas average heart rate had returned to placebo levels 75 minutes after injection of 0.022 mg/kg THC, heart rate after 0.044 mg/kg THC had not returned to placebo levels until after the 100-minute postinjection time.

Local-anesthetic administration in patients premedicated with THC had no significant effect on heart rate during or after the injection process. "Highs" experienced after THC premedication did not coincide with peak heart rates, peak tachycardia occurring typically 12 minutes before peak

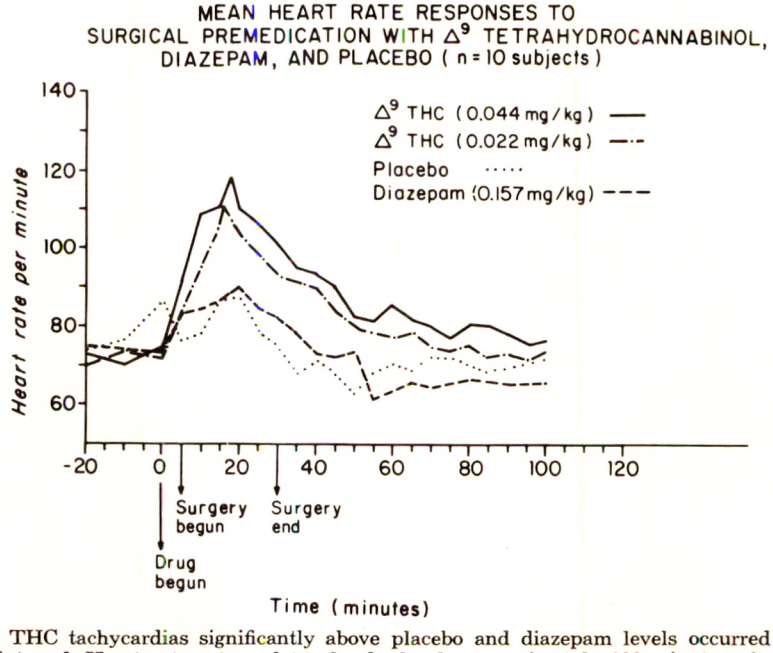

FIG 2. Peak THC tachycardias significantly above placebo and diazepam levels occurred at the 15-18 post-injection interval. Heart rate returned to placebo levels approximately 100 minutes after injection of THC, 0.044 mg/kg.

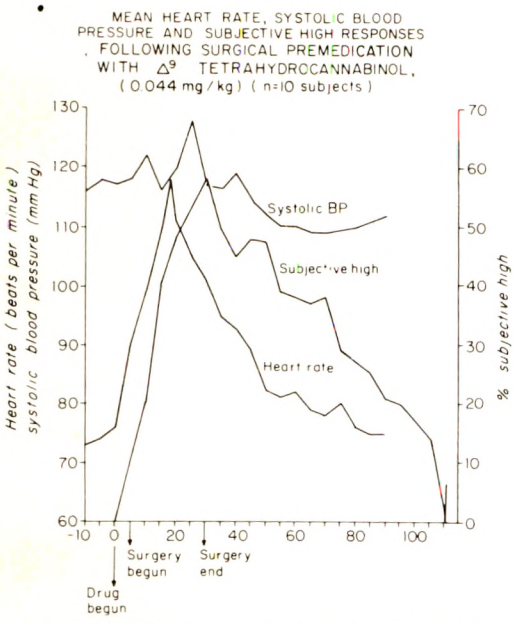

FIG 3. Simultaneous plotting of heart rate, blood pressure and subjective high responses to THC during surgery showed that peak tachycardia preceded both the peak hypertensive and subjective high effect, and that the heart rate and blood pressures returned to placebo baselines an average of 30 minutes before subjective high was reported as normal.

"highs." Heart rates also returned to placebo levels an average of 30 minutes before subjects reported a normal psychic state (fig 3).

ECG Responses.—There was a dose-related shortening of P-R interval greater than 33% in all subjects given THC (table 1). T-wave amplitude reduction of greater than 33% during peak drug effect was observed in 70% of subjects after the smaller doses of THC and in 60% of subjects after the larger THC dose, as compared to a 30% depression with diazepam and 10% depression with placebo. ECG changes in THC-premedicated patients were the same with local anesthetic injection as with placebo.

Arrhythmias, interpreted as functional premature ventricular contractions (PVCs), were observed in 11/40 clinical trials during baseline preoperative recording and in 2/10 subjects during intraoperative trial with placebo premedication. After injection of 0.022 mg/kg THC, arrhythmias seen preoperatively in 2 subjects increased slightly in frequency intraoperatively, and PVCs were observed in 2 other subjects who had not displayed arrhythmias during preoperative baseline recording. After injecting the larger dose of THC, arrhythmias observed in a single subject during baseline preoperative recording disappeared for an hour after drug administration and intraoperative recording (fig 4). No other instances of arrhythmia were observed after giving the larger dose of THC.

Surgical and Nonsurgical THC Groups Compared.—A significant difference ($p<0.05$) was seen in peak heart rate between oral surgery patients and nonsurgerized controls given comparable doses of THC (table 2), but no other significant cardiovascular differences were observed between these 2 groups.

Correlated Subjective Psychologic Effects.—STAI anxiety scores were significantly elevated ($p<0.05$) in THC-medicated surgery patients when compared with placebo or diazepam or with nonsurgerized THC

subjects. Dysphoria, as measured by SDEQ analysis, and "low" moods predominated at the periods of syncopal hypotension after THC.

STUDY 2: METHODS

This retrospective study included 10 consecutive patients, 7 women and 3 men (ages 21 to 30, mean 25 ± 3.1) undergoing outpatient general anesthesia for routine removal of from 2 to 4 third molars in one clinical procedure. Each patient was healthy and free of cardiovascular or respiratory abnormalities and gave informed consent.

At each clinical trial, patients were seated in the operating chair in an approximately 30° upright position with legs parallel to the floor. A venous catheter was inserted in the forearm. Physiologic monitoring consisted of continuous ECG, heart rate, indirect blood pressure, and respiratory rate, by a technic similar to that described for study 1. In addition, serial blood-gas measurements (IL* Blood Gas Analyzer) were made through radial-artery puncture, preoperatively and at selected intervals during operation.

After baseline blood pressure, ECG, heart rate, respiratory rate, and blood gases had been recorded, all 10 patients received the same form of general anesthetic management. First, 0.4 mg of atropine sulfate was administered IV, followed by 0.1 mg of fentanyl. Ten to 15 mg of diazepam was then infused over a 6 to 8-minute period to an endpoint of hypnosis with Verrill's sign (lid lag over pupils). After adequate sedation, N_2O-O_2 (70:30) was administered through a McKesson nasal inhaler by a McKesson Analor® gas machine. After 15 to 30 seconds, 1% sodium methohexital was given at a rate of 20 mg/30 sec until voice contact with the patient was lost.

Following induction, respirations were gently assisted with nasal insufflation, and additional increments of methohexital were infused as needed. Tooth extraction then proceeded according to standard technic, including mouth gauze packing and the PRN administration of local anesthetic blocks. The total usual dose of local anesthetic ranged from 4 to 6 ml of 2% lidocaine (80 to 120 mg) with 40 to 60 mcg of 1:100,000 epinephrine.

Surgical anesthesia ranged from 25 to 45 minutes in duration. No major complications were encountered. Following awakening, patients were monitored for a minimum of 1 hour before discharge.

STUDY 2: RESULTS

Of the 10 patients studied, 5 admitted to having smoked marijuana within 72 hours

*$p < 0.05$ mean differences smokers compared with nonsmokers.

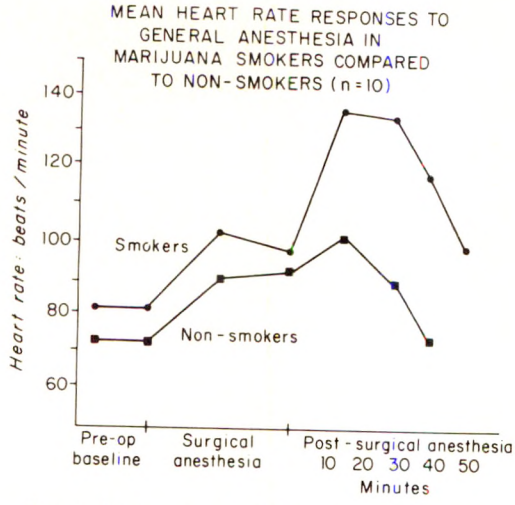

FIG 5. Tachycardia following general anesthesia was markedly elevated and lengthened in marijuana smokers as compared to non-smokers.

of operation. A comparison of cardiovascular responses between marijuana-smoker and nonsmoker groups revealed similar preoperative baselines of blood pressure, heart rate, ECG, and blood gases (table 3). In addition, blood pressure responses and blood gases were found similar and within expected limits for both groups throughout the duration of anesthesia and the postoperative period.

A major difference between the 2 groups was observed, however, in heart rate response during the postanesthetic interval (fig 5). In the marijuana group, a peak tachycardia averaging 64.8% above baseline occurred, which did not return to baseline levels until an average of 38 minutes after the end of anesthesia. In the nonsmoker group, postoperative heart rate peaked at 39% above baseline at the 7-minute mark after anesthesia and returned to baseline levels by the 19-minute mark after anesthesia.

There were no significant differences between smoker and nonsmoker groups for total required methohexital (193 versus 194 mg). Nor were there differences between mean "sleep time" induced by these concentrations (32.4 versus 31.8 min) or in recovery rate.

DISCUSSION

In the current studies, which involved healthy young adults, there was no significant deterioration in cardiovascular functions. However, certain changes were observed that might hold significance for other patient populations.

Transient syncopal hypotension followed THC premedication. (Psychologic measures during these periods demonstrated above-average levels of dysphoria and anxiety.) These patients did not demonstrate syncope when premedicated with placebo or diazepam. Orthostatic hypotension and presyncopal responses to table tilt have been described as common with THC.[31,32] Controlled animal experiments have shown that stress exaggerates an already elevated sympathoadrenal response to parenteral cannabinols, manifest as marked elevations in serum dopamine hydroxylase levels.[25]

Beaconsfield first warned that under stressful or emergency conditions, the vasomotor reflex mechanisms may be significantly impaired in marijuana-pretreated subjects.[14,33] He demonstrated that peripheral blood flow increases concomitantly with pulse rates following cannabinol administration, and that peripheral flow adjustments to mild psychogenic stress (mental arithmetic and ice placed on a limb) are markedly slowed or absent. Careful cardiovascular monitoring, therefore, is mandatory following THC premedication.

After the initial tendency to syncopal hypotension from THC during operation, the blood-pressure response displayed a biphasic pattern of mild hypertension, which peaked at the 25-minute postinjection interval, followed by a gradual hypotensive trend which reached its peak depression at 55 minutes postinjection. Surgical stimulation probably had a strong influence on blood-pressure response. However, similar arousal-depression patterns have been observed in nonsurgical experiments with cannabinols, and there may be pharmacologic reasons for this pattern:[17] As Δ^9-THC undergoes biotransformation to the more polar form, 11-OH-Δ^9-THC, within 10 to 15 minutes after injection, it has been suggested that Δ^9-THC exerts a generalized CNS and cardiovascular arousal effect, and that 11-OH-Δ^9-THC has a longer-acting depressant effect.[34]

In our study, combining THC premedication with the stress of oral surgery appeared to have a synergistic effect on heart rate, since subjects who had received 0.044 mg/kg of THC before operation reached peak heart rates averaging 24.1% higher than the peaks for the nonsurgerized controls. These observations are consistent with current theories

of the mechanism of THC cardiovascular action. Studies have suggested that vagolytic action by the cannabinols is unlikely because cannabinol tachycardia is inducible even in atropinized patients.[14] Most evidence points to a CNS-activated sympathoadrenal response to cannabinol. Beta-adrenergic receptors appear to be the final common pathway for this response, since propranolol, a beta blocker, reduces the effects of cannabinol.[35]

Even though THC tachycardia appeared to be heightened by the stress of operation in this study, it is of interest that the initiation and duration of heart rate changes appeared to precede psychic effects. Onset of heart rate elevation consistently preceded the onset of "highs" by a few minutes, and the peaks of heart rate and subjective "high," as well as the duration curves, were generally out of phase by a matter of many seconds to a few minutes. This finding is consistent with those of Low's group,[13] who observed that subjective THC effects may persist even though heart rate has returned to normal.

It may be speculated that the inevitable THC tachycardia acts as a partial trigger for the psychic effect of cannabinols, and that the surgically stressed patient reacts to tachycardia in a manner different from the nonstressed THC subject. Whereas the nonstressed subject interprets THC tachycardia as an expected and nonthreatening aspect of his drug experience, the stressed patient considers it a signal that is part of an overall harmful situation (the operation) which is out of his control. This activates the hypothalamo-pituitary complex and eventually a classic sympathoadrenal stress response, which then potentiates the preexisting THC tachycardia.

In pursuing one of the goals of the current study, the detection of significant drug interactions between cannabinols and a local anesthetic agent, it was observed that usual surgical levels of 2% lidocaine and 1:100,000 epinephrine had no measurable effect on any cardiovascular parameter. Beaconsfield[33] has shown that THC potentiates the pressor effects of IV epinephrine in humans, while laboratory studies[32,36] have shown elevation of circulating epinephrine for periods of 6 hours following THC administration. It would appear, however, that the doses of lidocaine and epinephrine used in our studies with surgery patients and with routine anesthetic block were insufficient to interact significantly with cannabinol premedication.

An apparent drug interaction was observed, however, in study 2 of this investigation, where a prolonged postoperative tachycardia was observed in a series of patients who had smoked marijuana within 72 hours before undergoing outpatient general anesthesia. Not only is this a potentially dangerous problem, but when the etiology of the tachycardia is not appreciated, errors in medical management may occur.

Previous studies[14] have demonstrated synergistic cardiovascular effects between cannabinols and vagolytic agents. This suggests that atropine, used in the current anesthetic technic, was the drug most likely to have interacted with the previously smoked cannabinol.

Potential drug interactions occurring many hours, or even days, after marijuana smoking appear quite possible, in light of the known distribution, catabolism, and excretion patterns of the cannabinols. Plasma levels of $\triangle^9$-THC decrease rapidly after injection, probably because of a great affinity for fat stores.[37] THC may also be stored in significant quantities in the enterohepatic tissues and be secreted along with bile in response to food ingestion.[9] Although this appears to be the primary means of cannabinol excretion, with 70 to 80% eliminated in the feces and 20 to 30% in the urine, the enterohepatic secretion, with subsequent plasma resorption from the gut, may also account for the frequently observed maintenance of sustained and episodic THC plasma levels.[38]

The plasma half-life of $\triangle^9$-THC is 36 hours; that of the active liver metabolite, 11-OH-$\triangle^9$-THC, is 40 hours. The release of active THC compounds has been shown to continue for 8 days after a single human dose.[7,34] Therefore, 20 to 35% of active cannabinols may remain in the tissues for longer than 72 hours after a single administration. This time course is quite compatible with the sequence of drug interactions suggested by our study 2.

An acute dose-related antiarrhythmic effect was observed during oral surgery with THC premedication. The smaller doses of $\triangle^9$-THC were associated with intraoperative PVC activity at levels similar to those of placebo, whereas the larger doses were correlated with the disappearance of arrhythmias after injection. Although some

authors[17,20] report possible induction of arrhythmias by cannabinols, other observers[21,39] have shown possible antiarrhythmic effects. In our study, arrhythmias were of the benign variety, consisting mainly of transitory ectopic foci. It would be unwise to assume that a similar therapeutic effect would have occurred in a group of patients with chronic cardiopathy.

We conclude that Δ^9-THC has no particular advantage over diazepam or placebo as a premedicant; although potentially therapeutic antiarrhythmic effects were seen, THC appeared to compromise to some degree the surgical patient's adaptivity to stress and to interact undesirably with other anesthetic medications.

TEMPERATURE AND d-TUBOCURARINE The influence of temperature (28-41C) on d-tubocurarine (dTc) neuromuscular blockade and antagonism with neostigmine was studied in anesthetized cats. dTc infusion rate required to maintain 90 per cent twitch depression was directly related to temperature. Although the mechanism is not known, reduced renal and biliary excretion of dTc, may account for the decreased dTc needs during hypothermia. Hypothermia did not affect the magnitude but prolonged the onset and then duration of dTc antagonism by neostigmine. Since hypothermia reduces skeletal muscle blood flow the delayed uptake and elimination of neostigmine should not be unexpected. *(Miller RD, Van Nyhuis LS, Eger EI: The effect of temperature on a d-tubocurarine neuromuscular blockade and its antagonism by neostigmine. J Pharm Exp Ther 195:237-241, 1975)*

Management of a Parturient with Cardiac Valve Prosthesis

DEMIR M. SAKA, MD*
GERTIE F. MARX, MD†
Bronx, New York‡

The parturient with a cardiac valve prosthesis presents a twofold problem of management: (1) that of a rising cardiac workload in the presence of serious heart disease, and (2) that of chronic anticoagulant therapy. Pain relief, a shortened 2nd stage of labor, and avoidance of bearing-down efforts reduce stress. Vaginal delivery is preferred to cesarean section, and segmental lumbar extradural block is the optimal anesthetic method. Oxytocics must be used with caution and heparin is preferred to long-acting oral anticoagulants.

A 24-YEAR-OLD hemiparetic woman, a known rheumatic cardiac patient with a mitral valve replacement, came to our emergency room with a vague history of amenorrhea and complaints of low back pain, abdominal discomfort, and breast fullness. She was 4 months pregnant and desired continuation of the pregnancy. She was admitted to our prenatal unit for continued care until delivery.

At 5 years of age, she had had rheumatic fever, but maintained a normal life until the age of 19, when she had a cerebrovascular accident. A diagnosis of mitral stenosis was made and she was placed on anticoagulant therapy. Cardiac catheterization 1 year later revealed the presence of mitral and aortic insufficiency in addition to mitral stenosis, and mitral commissurotomy and valvuloplasty were performed with good result.

Ten months later, she injected heroin with an unclean syringe and developed *Staphylococcus aureus septicemia*, leading to acute bacterial endocarditis which primarily affected the mitral valve. Emergency mitral valve replacement was undertaken. For the 4 years prior to the present admission, she was on maintenance doses of digoxin, furosemide, and hydroxycoumarin, and had successfully withdrawn from narcotic addiction.

Physical examination revealed a chronically ill patient with left hemiparesis, walking slowly with the aid of a cane. She developed dyspnea on minimal exertion and was classified as an AHA class III heart patient. Blood pressure was 120/70 torr, heart rate 80 to 90 and grossly irregular. Auscultatory findings were commensurate with the presence of a mitral prosthetic valve and aortic insufficiency. An ECG showed atrial fibrillation with occasional premature ventricular contractions.

Throughout her stay in the hospital, the patient was on a low-sodium diet and was taking digoxin, diuretics, iron sulfate, and anticoagulants (sodium warfarin until the 36th week of gestation, heparin 5000 units every 6 hours thereafter).

The pregnancy progressed satisfactorily. One episode of congestive heart failure during the 2nd trimester was treated successfully with increased doses of digoxin and furosemide. At 39 weeks of gestation, the patient was considered ready for delivery

Paper received: 7/21/75
Accepted for publication: 8/8/75

(the cervix was favorable for induction and the fetus was mature). Accordingly, heparin was discontinued, kanamycin and penicillin administered intramuscularly, and membranes ruptured artificially. Regular contractions began 3 hours later.

A slow IV infusion of 5% dextrose in 1/3 NaCl (50 ml/hr) was started, and blood obtained for cross-match, clotting time, and prothrombin time determination. Clotting time (Lee-White) was 26 minutes and prothrombin time 21 seconds (control 11.5). Protamine sulfate (total of 25 mg) was given in increments until coagulation values became and remained normal.

As soon as cervical dilation permitted, internal monitoring of uterine pressure and fetal ECG was begun. At 5 cm dilation, a continuous lumbar extradural block was initiated using a 17-gauge thin-walled Tuohy needle and a Teflon-styleted catheter, which was threaded cephalad. The patient's right hip was elevated by a foam-rubber wedge (to prevent aortocaval compression), and O_2 was administered continuously by face shield. For pain relief of the 1st stage of labor, a segmental block from T9 through L1-2 was achieved with 2% 2-chloroprocaine, using a total of 360 mg over a 2¼-hour period. Chloroprocaine (3%, 6 ml) injected in the sitting position provided perineal analgesia.

A normal healthy infant (Apgar scores 8 to 10) weighing 3050 gm, was delivered by low-mid forceps over a mediolateral episiotomy after 45 minutes of 2nd-stage labor. Synthetic oxytocin (10 units) was added to 500 ml of IV fluid after expulsion of the placenta. Blood loss was less than 250 ml, and vital signs remained stable (BP 120/70 to 110/60, heart rate 96 to 108 during labor, 88 postpartum). Following repair of the episiotomy, another 6 ml of 3% chloroprocaine was administered, resulting in a sensory level of T8 and producing analgesia for bilateral tubal ligation (through a 5-cm subumbilical incision, with blood loss of 20 ml).

Lead II of the ECG was monitored throughout the course of extradural block and showed unchanging atrial fibrillation. There appeared to be no danger of postpartum cardiac failure, and the extradural catheter was removed at the end of the operative procedure. Heparinization was restarted 24 hours later, and the mother ambulated shortly thereafter. Both mother and infant had an uneventful course.

DISCUSSION

The pregnant woman with cardiac valve prosthesis presents a twofold problem of management: (1) that of a rising cardiac workload in the presence of serious heart disease, and (2) that of chronic anticoagulant therapy.[1] Cardiac output and left ventricular work, which rise steadily during gestation, are further increased during each effective uterine contraction.[2] However, their cumulative increases can be significantly reduced by adequate pain relief, a shortened 2nd stage of labor, and avoidance of bearing-down efforts.[3,4]

It has been stated that the ideal delivery for the parturient with acquired heart disease is "one which is accomplished using simple outlet forceps under some form of regional anesthesia," preferably continuous extradural block.[4] Segmental lumbar extradural analgesia is optimal because pain relief is specific while the disadvantages of more extensive blockade are prevented; yet the technic can be employed to reduce venous return to the heart, should cardiac failure with pulmonary edema suddenly occur. We chose chloroprocaine as the local anesthetic because of the versatility and safety offered by its short duration of action.

It is evident that hypotension should be avoided. However, blood pressure ought not decline significantly or at all, if a segmental block is executed judiciously and compression of the inferior vena cava circumvented. If, nevertheless, vasopressor treatment becomes necessary, the choice of drug depends upon the cardiac disease. Although ephedrine is preferred from the viewpoint of the fetus, it is contraindicated whenever increases in cardiac output and/or rate are harmful to the mother. In such situations, a dilute solution of phenylephrine or norepinephrine is recommended.

Oxygen inhalation by face shield or nasal cannula is beneficial in view of the increased O_2 consumption associated with labor, and administration of broad-spectrum antibiotics is advocated as prophylaxis against the development of bacterial endocarditis at parturition. Oxytocics must be used with caution. Ergonovine-type drugs are vasoconstrictors which raise venous and arterial pressures, whereas the synthetic oxytocins are vasodilators capable of producing marked hypotension. Only a dilute solution of a synthetic oxytocin should be administered to a cardiac patient.

Heart disease, per se, is no indication for

cesarean section. Despite the repetitive hemodynamic alterations caused by labor, vaginal delivery offers advantages to both mother and neonate. The mother benefits from lesser blood loss, lesser danger of wound infection or dehiscence, lesser hazard of thrombophlebitis, and lesser incidence of bleeding following reheparinization; the infant, from more physiologic preparation for extrauterine life.

Anticoagulation constitutes a special problem during pregnancy. The long-acting oral anticoagulants, consisting of small molecules, traverse the placenta freely, with possible teratogenicity and hemorrhagic potential in placenta and fetus.[1] In addition, reversal of their effect is slow. They should not be used during the 1st trimester or near term. Instead, heparin, which does not pass the placenta and can be reversed easily, should be employed in the beginning and in the last 4 to 6 weeks of gestation. At the onset of labor, heparin should be discontinued and reinstituted 24 hours after delivery. Within 5 to 7 days postpartum, oral anticoagulants can again replace heparin.

Because of a recent case report of extradural hematoma formation in a patient with occlusion of the popliteal artery, who was started on heparin therapy 20 minutes after initiation of a continuous extradural block,[5] we did not reheparinize our patient until 24 hours after removal of the catheter.

The long-standing hemiparesis was not considered a contraindication to extradural analgesia, as it was the result of embolization from mitral stenosis, a disease process eliminated since, and did not represent a neurologic disease with the potential of progression or exacerbation.

CSF AND CEREBRAL ANOXIA Changes in cisternal and lumbar cerebrospinal fluid (CSF) were measured to determine metabolic changes in the central nervous system after profound anoxia. In 12 patients who could not be resuscitated the cisternal CSF pH was more acid and the potassium concentration double that in lumbar CSF. These data suggest that potassium and hydrogen ions leave the brain cells during anoxia and these changes are more accurately reflected by cisternal than lumbar CSF. Marked increases in extracellular fluid potassium may produce vasoconstriction and impair re-establishment of regional cerebral blood flow following ischemia. Cisternal CSF was normal in a group of patients who were successfully resuscitated. *(Kalin EM, Tweed WA, Lee J et al: Cerebrospinal-fluid acid-base and electrolyte changes resulting from cerebral anoxia in man. NEJM 293:1013-1016, 1975)*

A Potential Ignition Source in the Operating Room

EDWARD F. ANDERSON, LCDR, USN (MC)*

Close proximity or point-to-point contact between the posterior aspect of the light in the Castle/Daystar® lighting system and the O_2 supply tubing can result in the development of hypoxia or in an explosion, as described in the following case report.

BECAUSE of the decrease in use of flammable anesthetic gases and vapors, there has been a corresponding decrease in concern as to the possibility of fires and explosions in the operating room.[1] However rare, fires and explosions still occur, as was demonstrated by a recent report of a flash fire after the use of a skin prep spray and electrocautery.[2]

An unusual potential ignition source in the operating room is described in the following case report.

CASE REPORT

The patient was a 64-year-old ASA class II woman having an exploratory laparotomy. General endotracheal anesthesia, using a balanced technic consisting of N_2O-O_2, meperidine, and d-tubocurarine, was administered.

Approximately 2 hours after the incision, the orbiter lights of the Castle/Daystar® Surgical Lighting System were adjusted for better lighting in the operative field. Ten minutes after the above placement, a loud "pop" was heard, followed by a continuous, loud "hiss." The posterior aspect of one lamp was found to be 3.8 cm from the O_2 supply tubing, at a point 15.2 cm from the O_2 outlet in the overhead console above the anesthesiologist. The O_2 tank was turned on, after which the O_2 supply tubing was disconnected from the outlet. A 1-cm-long break (figure) was noted in the O_2 supply tube, with no observable melting of the material. No damage or injury to the patient or operating room personnel occurred, and the operation continued without further incident.

DISCUSSION

Despite the decrease in use of flammable anesthetics, fire and explosions are still a threat. Many items used in the operating room are flammable, including: "gauze pads and sponges, adhesive tape (especially plastic), eye patches, drapes, prepping solutions, and rubber endotracheal tubes."[1] When combined with a source of ignition and increased concentrations of O_2 or N_2O, fires and explosions are possible.

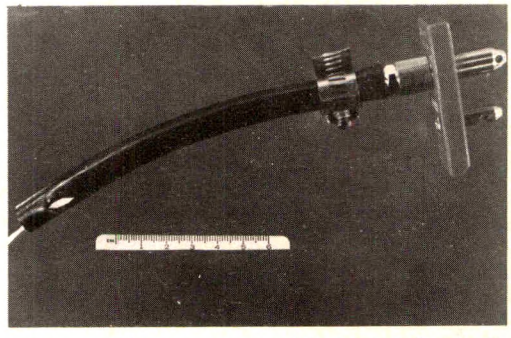

FIGURE. White arrow (at left) shows defect in O_2 supply tubing.

*Staff Anesthesiologist, Assistant Head, Department of Anesthesiology, Naval Regional Medical Center, Great Lakes, Illinois 60088.

The opinions expressed in this paper are those of the author and do not reflect the views of the US Naval Regional Medical Center, Great Lakes, the Bureau of Medicine and Surgery, or the US Navy.

Paper received: 6/25/75
Accepted for publication: 8/4/75

The O_2 supply outlet in the case described above was up beyond the 1.5-m hazardous area,[3] and the supply tubing was conductive; thus both conformed to the standards for the use of inhalation anesthetics.[4] The Castle/Daystar system gives color close to true daylight on the operative field, while transmitting "substantially less heat in the surgical field per foot candle of illumination." The cold mirror reflectors and optical train direct the high-intensity visible light to the field and about 80% of the infrared energy upward through the backs of the reflectors away from the surgical field.[5]

The O_2 tubing was manufactured by the Chemetron Corporation. It was composed of vinyl plastic, had a melting point of approximately 315 C, a bursting pressure of 325 psi, and had been in use for 6 months.

To determine whether the above incident could be reproduced, other tubing was placed in soft, point-to-point contact against the central rear surface of the orbiter light with the O_2 flowing at 2 L/min. Tubing from another machine had a blowout in 55 seconds. Fresh, unused tubing blew in 65 seconds with the light in question and in 67 seconds with another orbiter light.

Increasing the temperature of the O_2 supply tubing progressively weakened the walls until they were no longer capable of supporting the moderate pressure (50 psi) at which the O_2 is supplied. The resulting "blowout" could lead to the development of hypoxia (should the O_2 tanks not be turned on) by allowing the O_2 to escape through the lower resistance hole into the operating room atmosphere. Furthermore, if there were direct contact between the O_2 tubing and the posterior of the lamp or if flammable anesthetics or other combustible substances were present with an elevated temperature, an explosion might have occurred.[6]

SUPRASTERNAL PALPATION Measurements of tracheal length (inspiratory chest radiographs) in non-intubated infants revealed the tracheal midpoint to be within 0.5 cm of the interclavicular midpoint. With the head in a neutral position, an endotracheal tube with stylet is passed through the glottic opening until the tip is palpated in the suprasternal notch at the level of the clavicles. Thirteen intubations performed with external tracheal palpation were confirmed to be within 1 cm of the interclavicular midpoint while only 3 of 14 tracheal tubes were so placed without external palpation. Auscultation was unreliable as the distal end of the tracheal tube could be 1 cm in either bronchus without changes in breath sounds. Disadvantages of this technique include the need for two people and the use of a stylet. *(Bednerek FJ, Kuhns LR: Endotracheal tube placement in infants determined by suprasternal palpation: A new technique. Peds 56:224-229, 1975)*

In each issue of the Journal an article of particular interest and value to anesthesiologists, which has been published elsewhere, will be presented. Primarily the material will contain fundamental basic information which has been presented by anesthesiologists, physiologists, pharmacologists, and others and, on occasion, by commercial firms. Righting the Wrongs of Writing: Copy Editors Speak Out

JACLYN J. ALEXANDER
JUDY WALL

The major part of APGA Press production editor's jobs is copy editing manuscripts before they are set in type. In this article, written at the invitation of the P&G editor, two APGA Press Staff members use specific examples to illustrate the grammatical and stylistic errors that cause problems for them and, if not corrected, for readers. The authors hope that contributors and potential contributors to professional journals will find this article helpful in expressing their ideas clearly when preparing material for publication.

IT'S A typical day in the Press Staff offices.

The managing editor's phone rings.

"APGA Press."

"Jackie? It's Jude. I can't figure out this sentence."

"Okay, read it to me."

"It says, 'It has been thusly observed that students in contiguous areas of growth at various levels, no matter where they are, come to the counselor for help with the presumptuousness of effectiveness of facilitation.' "

"What???"

"Well, I have no idea what these authors are talking about."

"What's the article about?"

"It's about the characteristics of undergraduate students who seek counseling."

"All right, let's take it one step at a time. What does the pronoun *they* refer to? Students? Areas? Levels?"

Jaclyn J. Alexander is Managing Editor of the APGA Press and has been copy and production editor for several of the APGA divisional journals. Judy Wall is Senior Editor on the APGA Press Staff and copy and production editor of the PERSONNEL AND GUIDANCE JOURNAL. The authors express their thanks to Richard Wall for his help in the revising and polishing of the manuscript (despite their advice in this article to have manuscripts critiqued by objective outsiders).

Copyright (1975) American Personnel and Guidance Association. Reprinted with permission.

TEN MINUTES LATER:

"Okay, read it back to me. What have we got?"

"Here it is: 'We have seen that students at all levels of growth come to the counselor for help and expect to receive it.' "

Conversations of this kind take place often around the APGA Press. In this case we were able to figure out what the authors wanted to say and help them say it clearly. We can't always. Sometimes a sentence is so awkward that we don't know what the author is trying to say, and chances are that the reader won't either. We thought it might be helpful to share with P&G readers and potential contributors some of the misuses and poor uses of language we have come across in articles we have edited. By being aware of some of the common writing faults that can lead to misinterpretation, an author can avoid them.

WHY COPY EDITORS?

Copy editors, those mysterious, behind-the-scenes people on the staffs of every book publishing company, magazine, journal, and newspaper, have a major job: to help writers communicate their ideas to readers as clearly and effectively as possible. Essentially this process entails improving readability by correcting grammatical errors and making stylistic changes. Depending on the literary medium they are working in, copy editors' tasks vary. Although our experience has been primarily in journal work, and our examples are drawn from this medium, what we have to say is applicable to all types of writing.

A professional journal article is expository in nature. The author's purpose is to present a point of view, an idea, a finding, or a program to a readership of professional colleagues. In other words, the article is designed to inform. To communicate. To talk to people. When the writing technique or style interferes with or detracts from the ideas, the purpose is defeated.

This is where we come in. On the following pages are some examples of the kinds of changes we make in manuscripts to clarify meaning and improve readability.

RIGHTING THE WRONGS OF WRITING

There are two types of problems that give copy editors headaches. One is that of grammar and syntax—a misplaced comma, an incorrectly used conjunction, a pronoun with an unclear referent. The other, harder to define, concerns style and readability. We'll take the second one first.

STYLE AND READABILITY

Some years ago, a newscaster reported on a national news station, "He shot his girlfriend in the Bronx." If you've ever been shot in the Bronx, you know how painful that can be.

Okay. Everybody knew what he meant; the point is that it sounded a little silly. Style is not what you say but how you say it. Remember, the purpose of professional journal material is to communicate. Anything—a paragraph, a sentence, a phrase, or even a word—that doesn't work smoothly to that end doesn't belong there. There are several ways that style can interfere with communication.

Short and Sweet Says It Best.—Writing principle number one, and also principles number two, three, and four, is *economy of expression.* No matter what the medium, the straightforward, declarative sentence is the most direct way of communicating. You can't beat it. Unnecessarily long and involved sentences only confuse readers. Such sentences crop up when an author tries to cram too many ideas into one sentence. When a sentence has too many clauses, too many "whiches," the reader tends to try to sort out the sentence instead of paying attention to what the author is saying. Sentences needn't be choppy, but they shouldn't be so complicated that the reader must read them two or three times to understand the meaning.

The following is a good example. "The client who has been referred within himself or herself predetermines and verbalizes to the counselor to whom he or she has been referred about what his or her counterproductive behaviors are or are not, makes decisions regarding which of such behaviors she or he can commit himself or herself to work on, with the counselor, of course, and the counselor facilitates the setting of aforementioned goals related to the replacement of such with more positive behavioral performances, or goals related to the acquisition of such which had not previously been within the viable parameters of the client's activity-oriented repertoire." Whew. Authors may know what they mean when they write sentences such as that one, but, being more involved with their ideas than with their words, they don't express the meaning succinctly and clearly.

Where language and diction (word choice) are concerned, economy of expression is again the key. Unusual word usages are detrimental to communication when they draw attention to themselves and away from the writer's ideas. When a short, simple, common word will do, use it in place of a long, unusual one. Why send readers scurrying to their dictionaries to look up *perdure* and *extirpate* when *last* and *destroy* will convey the meaning? The impression this gives is that the author is trying to impress readers with an extensive vocabulary. They may indeed be impressed. They may also miss the author's meaning. Using simple words is not necessarily patronizing. Rather, it makes for clear, precise, direct communication.

Another diction fault may have the opposite effect: It may put readers to sleep. We're talking about the tendency to repeat the same word or phrase over and over again. Using interesting synonyms makes uninteresting writing more interesting for interested readers. Oops. What we meant to say was that the use of interesting synonyms makes dull writing come alive for attentive readers.

Writing in Action, or, Action in Writing. A problem on the more technical side is the use of the passive voice. Here's a quick grammar lesson, before you go hunting for your fifteen-year-old's grammar text in order to get through this paragraph. *I taught the class* has an active verb. *The class was taught by me* has a passive verb. Both sentences are grammatically correct, and in both the meaning is clear. The difference is in the emphasis. In the second case the grammatical subject of the sentence is not the person who is doing the acting (*me*) but the thing that is being acted on (*the class*).

We've seen many articles full of good ideas that might have been interesting but weren't because sentence after sentence had passive verbs. This kind of writing is boring and dry because it is literally passive; there is no action taking place, no movement to keep the reader interested. Unfortunately, this is the least of the difficulties. Often a sentence written in the passive voice is at best ridiculous, at worst incomprehensible. One author wrote, *Courses are taught by the counselors in mental institutions.* The copy editor changed it to read *The counselors teach courses to patients who are in mental institutions,* lest young counselor trainees get the wrong impression about what will happen to them after they get out of school. *Counselors and students plan a curriculum together, and a student portfolio is maintained.* Obviously, it is not clear who is keeping the portfolio. Are counselors keeping tabs on the students? Are students recording their own progress? Or is a third party keeping this log? This is a case in which the active voice is imperative for clarification.

In other words, don't say *it can be seen that;* say *we can see that.* Don't say *it is hoped by this author that;* say *I hope that.* Don't say *it has been shown by researchers that;* say *researchers have shown that.* In your reading, watch for passive construction and see how it detracts from the impact of a sentence. Watch for it also in your writing, and change it!

The Medium, the Message, the Method. A more general style issue authors should be concerned with is the appropriateness of language. Metaphors, analogies, images, and poetic phrases are often inappropriate in expository writing because they are distracting. As with unusual word usages, these figures of speech draw attention to themselves. We have come across sentences such as these in journal manuscripts: *In order to relate to clients, the counselor must empathically wear his heart on his sleeve.* Sounds pretty messy. *The book provided a veritable treasure chest of pearls of wisdom for those who read it.* A real gem. *Driving down the narrow and winding highway of life, we counselors have a panoramic view of the lonely, alienated counselee-hitchhikers who beckon to us to stop and help them. Will we heed the call of their supplicating thumbs?* Good grief.

Imagery and poetic language work only when they are fresh, interesting, and to the point. Words and phrases that are trite don't work in any context. Only the most skillful writers can combine expository and creative writing without causing a jarring effect on the reader.

We can't leave this topic without saying a word about professional jargon. In many cases counseling terminology has specific meaning, and people in the field understand it. But many times a word or phrase is

"A professional journal article is designed to inform. To communicate. To talk to people. When the writing interferes with the ideas, the purpose is defeated."

overblown; the writer could substitute a simple word or phrase without sacrificing the meaning. In speaking of jargon, Edwin Newman, in *Strictly Speaking: Will America Be the Death of English?*, says, "A large part of social scientific practice consists of taking clear ideas and making them opaque" (1974, p. 146). He goes on to say,

> For a social scientist to make obscure what he considers to be unnecessarily clear calls not so much for an imagination as for an appropriate vocabulary in which boundaries are parameters, parts are components, things are not equal but co-equal, [and] signs are indicators. . . . To know oneself is to have self-awareness, communities being studied are target areas, thinking is conceptualization, patterns are configurations, and people do not speak but articulate or verbalize; nor are they injured: they are traumatized. . . .
>
> You can move on quickly to more complex constructions. "Siblings are conflicted in their interpersonal relationships" means that children of the same parent or parents don't like each other. "Exogenous variables form the casual linkage that explains the poverty impact, the behavior modification, and the intergroup dissonance in the target area" means that outside factors cause the poverty and the changes in people that lead to trouble in the neighborhood. A recommendation by a medical ethicist that a physician obtain an input from the patient's own value system means that the patient should be asked whether he wants the treatment. (pp. 146-147)

We don't mean to discourage the use of professional terminology when it is called for; we only urge that your writing be clear, simple, and direct. The use of jargon may muddy your message.

GRAMMAR AND SYNTAX

The mighty comma! This little piece of punctuation has the power to change the entire meaning of a sentence. *The counselor trainee the supervisors observed was having difficulty in applying behavior modification techniques* means that the supervisors observed a particular trainee who was having this difficulty. *The counselor trainee, the supervisors observed, was having difficulty in applying behavior modification techniques.* The commas give a completely different connotation to the word *observed.* Without the commas, *observed* is being used in the sense of "saw" or "watched"; with the commas, it means "made an observation" or "said."

Here's a case in which the meaning is clear, but only after a second reading of the sentence. *The group counseling sessions are cancelled today and tomorrow classes will start late.* These are two independent clauses separated by a conjunction; this construction almost always requires a comma. Without a comma after *today,* the reader tends to link *today* and *tomorrow* before realizing the writer's intent. But be careful; what appear to be independent clauses may not be. *The group counseling sessions are cancelled today, and tomorrow will resume as usual.* We're all relieved to hear that, but the writer intended no such assurance. Two independent clauses have two subjects and two verbs. This sentence has one subject *(sessions)* and a compound verb *(are cancelled* and *will resume); tomorrow* is an adverb. The best way to rewrite the latter sentence is *The group counseling sessions are cancelled today and will resume tomorrow as usual.*

Pronouns without clear antecedents are inevitably confusing. *The teachers put the children's drawings on the walls, and the parents praised them for their originality.* It's not clear what the pronouns *them* and *their* refer to. The situation calls for either a repetition of the noun being referred to or a recasting of the sentence. The second clause should be either *the parents praised the children's originality* or *the parents praised the originality of the drawings* or *the parents praised the teachers for the originality of their idea.* We assume that the walls were secure enough not to crumble for lack of parental praise.

Syntax refers to the order and relation of the elements of a sentence. *Dr. Finch was among the department heads at the meeting.* If Dr. Finch is one of the department heads, the sentence would be better written *Dr. Finch was one of the department heads at the meeting.* If Dr. Finch was standing amidst a group of department heads, that should be made clear: *Dr. Finch was standing among the department heads at the meeting.* Another example of a syntactical problem: *The concept of psychological education in the university has changed drastically* must be changed to read either *In the university, the concept of psychological education has changed drastically* or *Psychological education in the university is a concept that has changed drastically.* A third example: *Wives had a greater desire to talk to a counselor than their husbands,* said one author, making it easy to see why the wives

---

" 'Wives had a greater desire to talk to a counselor than their husbands', said one author, making it easy to see why the wives needed counseling."

---

needed counseling in the first place. What the author meant was: *Wives, more than their husbands, wanted to talk to a counselor.* Another alternative: *Wives had a greater desire to talk to a counselor than did their husbands.*

The program included lectures on the rationale for career development and role playing. There are three possible meanings here, and the syntax of the sentence should leave no doubt as to which is correct. *The program included lectures on the rationale for career development and the rationale for role playing.* Or, *The program included role-playing exercises and lectures on the rationale for career development.* Or, *The program included lectures on role playing and on the rationale for career development.* The difficulty in the original sentence arises from the fact that the reader can't tell whether the noun *role playing* is the object of the preposition *on,* the object of the preposition *for,* or the direct object of the verb *included.*

The placement of adjectives can be critical. In the phrase *new students, faculty, and staff,* it isn't clear whether *new* refers to all three groups or to students only. If the writer means to refer to all three groups, the phrase can read either *new students, new faculty, and new staff* or *students, faculty, and staff, all of whom were new.* If *new* refers to students alone, it can read, *new students, the faculty, and the staff* or, even better, *faculty, staff, and new students.*

Our intention here was not to write a grammar and style book but to focus on some common faults that hamper readability. Be aware of these faults. Look for others as well. Be a critical reviewer of your own writing; question every word, every phrase, every sentence. But don't stop there. Since you, as an author, may be too close to your own writing to be able to look at it objectively and assess its quality, have someone else read and critique it. That someone should be a person outside your professional field, a person who can provide an honest and objective appraisal of your writing. An English instructor, a writer, or an editor would be ideal. And there are plenty of good books on style and usage, some scholarly, some entertaining, all informative and helpful. You'll find our favorites listed in the bibliography.

A FINAL WORD

Writing quality may be the deciding factor in a journal editor's accepting or rejecting a manuscript. In some cases a manuscript is of borderline acceptability in terms of content and originality, and if the writing is poor, that may be the factor that consigns it to the rejection pile. In other instances a manuscript is quite good with regard to content and originality but is so poorly written that an editor rejects it for that reason alone. A practitioner may indeed have a practical and workable technique, a truly innovative program, or a fresh insight into an accepted theory, but an editor may never discover it. It is unlikely that an editor who has to wade through context to get to content will be favorably disposed toward the material.

We have two suggestions. The first we've mentioned or implied as often as we could in this article: *Economize in expression.* In writing, there is no substitute for simplicity. The second suggestion, closely related to the first, is this: *Write the way you talk.* People don't usually talk in five-syllable words and multiclause sentences; and readers are, after all, seeing the written words of someone who is talking to them. Here's how to check it out: If you would feel uncomfortable saying aloud something you have written, your writing is probably stilted and unnatural. Say to yourself what you would say to another person, and then write it that way. You can do the polishing later.

And so, as we wend our wandering way toward that big editorial office in the sky, we fight with never-ending zeal to extirpate obfuscation and illuminatively elucidate the methodological method for ameliorating the causative determinants of linguistic malfeasance. . . .

The Interaction Between d-Tubocurarine, Pancuronium, Polymyxin B, and Neostigmine on Neuromuscular Function

LINDA S. VAN NYHUIS, AB*
RONALD D. MILLER, MD†
RICHARD P. FOGDALL, MD‡
San Francisco, California§

The interaction between pancuronium, d-tubocurarine, polymyxin B, and neostigmine was studied in the rat diaphragm-phrenic nerve preparation. Polymyxin B (5 μg/ml) did not affect twitch tension alone but decreased the pancuronium ED_{50} from 0.8 μg/ml to 0.32 μg/ml and the d-tubocurarine ED_{50} from 0.25 μg/ml to 0.15 μg/ml. Neostigmine (0.2 to 10 μg/ml) antagonized pancuronium or d-tubocurarine-induced depression of twitch tension. In contrast, neostigmine (0.001 to 0.2 μg/ml) augmented polymyxin B depression. Similarly, neostigmine (0.1 μg/ml) augmented combined polymyxin B-pancuronium or polymyxin B-d-tubocurarine depression of twitch tension. The authors conclude that polymyxin B potentiates the neuromuscular blockade from pancuronium or d-tubocurarine and that neostigmine further augments this block.

THE incidence of postoperative infections of the peritoneal cavity and surgical wounds may be decreased by irrigation with polymyxin B.[1-3] However, polymyxin B produces a neuromuscular blockade which neostigmine does not antagonize and may prolong.[1-3] Although neostigmine is an effective antagonist of d-tubocurarine (hereinafter "tubocurarine") or gallamine neuromuscular blockade,[4] it is not known whether neostigmine will antagonize combined block from both polymyxin B and tubocurarine or gallamine.

A recent case report[5] suggested that neuromuscular blockade from polymyxin B-pancuronium was enhanced rather than antagonized by neostigmine. This also was the first report of pancuronium block being prolonged by polymyxin B. Accordingly, we studied the neuromuscular interaction between pancuronium, tubocurarine, polymyxin B, and neostigmine.

METHODS

Hemidiaphragms with attached phrenic nerves were resected from exanguinated 250-gm male Sprague-Dawley rats.[6] The preparations were placed in a 50-ml bath of Tyrode's solution[7] at 27 C (pH 7.1). One end of the diaphragm was fixed and the other end attached to a force-displacement transducer. The nerve was stimulated supramaximally (duration = 1 msec; frequency 0.2 Hz) and resultant muscle twitches, which

were calibrated with weights, were recorded on a polygraph. Dose-response curves were obtained for neostigmine (N=6), polymyxin B (N=6), pancuronium (N=4), and tubocurarine (N=4) alone. Also the effect of neostigmine on either a polymyxin B (N=4), pancuronium (N=6), or tubocurarine (N=6) neuromuscular blockade was determined.

Lastly, the effect of neostigmine on either polymyxin B-pancuronium (N=5) or polymyxin B-tubocurarine (N=5) neuromuscular block was determined. Drugs were added to the bath only after the twitch had been stable for 10 minutes. Maximum depression of twitch tension was observed for at least 5 minutes, to insure a stable endpoint. Then, at least three washings were used to remove the drug from the bath.

When the twitch tension had returned to control for at least 10 minutes, the process was repeated until a complete dose-response curve was obtained. The order of drug dose administration was randomized.

Linear regression lines were compared by analysis of variance.[8]

RESULTS

Without other drugs present, smaller doses of neostigmine (0.3 to 0.5 μg/ml) increased and larger doses (1 to 2 μg/ml) decreased twitch tension (fig 1). The ED_{50} dose (the dose resulting in a 50 percent reduction in twitch tension) of polymyxin B was 23 μg/ml (fig 2). Polymyxin B (5 μg/ml) decreased the ED_{50} of pancuronium

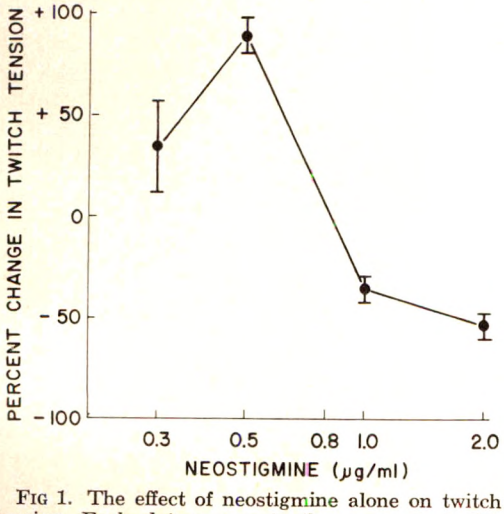

FIG 1. The effect of neostigmine alone on twitch tension. Each dot represents the mean ± 1 SE. (N = 6)

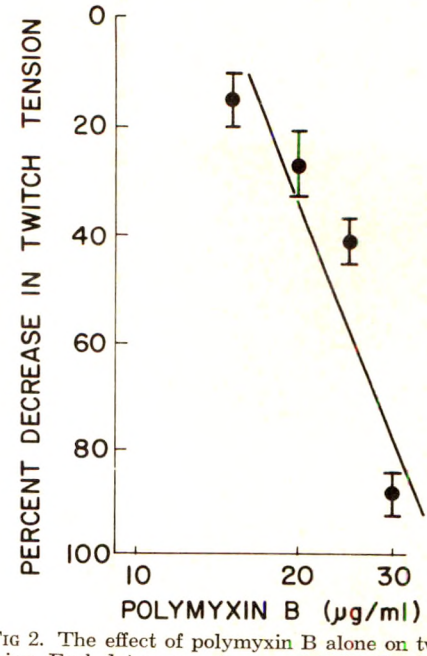

FIG 2. The effect of polymyxin B alone on twitch tension. Each dot represents mean ± 1 SE. The N = 6 on all doses except the 15 μg/ml dose, of which N = 4. ($r = 0.73$)

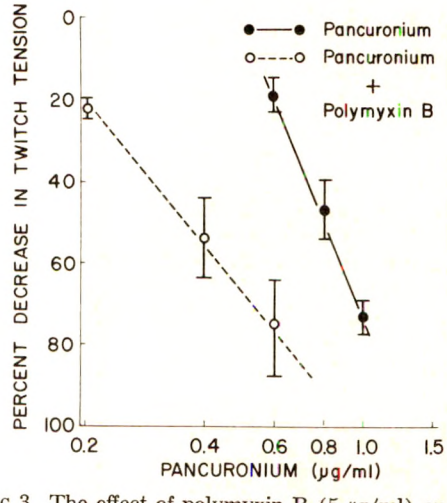

FIG 3. The effect of polymyxin B (5 μg/ml) on a pancuronium dose-response curve. The correlation coefficient for the pancuronium curve is 0.84 and for the pancuronium plus polymyxin B curve is 0.82. (N = 4)

from 0.8 to 0.32 μg/ml ($p<0.01$) (fig 3). Polymyxin B (5 μg/ml) decreased the ED_{50} of tubocurarine from 0.25 to 0.15 μg/ml ($p<0.01$) (fig 4). Although the pancuronium and pancuronium-polymyxin B dose-response curves were not completely parallel ($p<0.05$), the tubocurarine and tubocurarine-polymyxin curves were parallel.

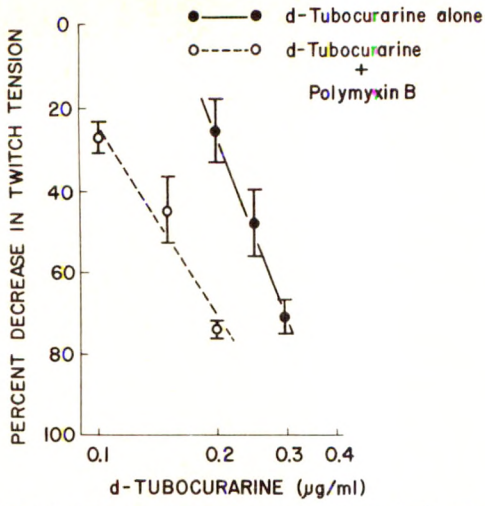

FIG 4. The effect of polymyxin B (5 μg/ml) on a tubocurarine dose-response curve. The correlation coefficient for the tubocurarine curve is 0.93 and for the tubocurarine-polymyxin B curve is 0.88. (N= 4)

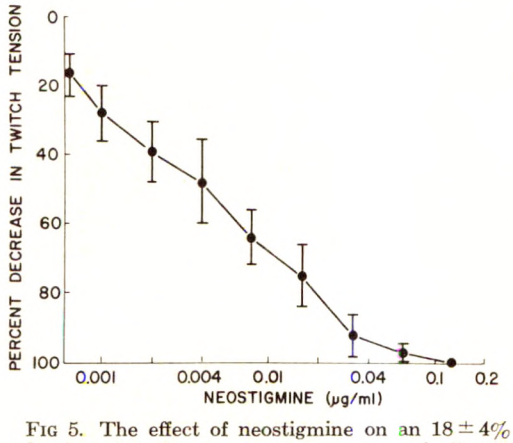

FIG 5. The effect of neostigmine on an 18 ± 4% reduction of twitch tension from polymyxin B (15 μg/ml). Each dot represents the mean ± 1 SE. (N= 4)

Neostigmine (0.001 to 0.15 μg/ml) progressively enhanced an 18 ± 4 percent block from polymyxin B (fig 5). In contrast, neostigmine (0.2 to 10 μg/ml) progressively antagonized a 73 ± 5 percent tubocurarine and 84 ± 5 percent pancuronium-induced depression of twitch tension (fig 6).

When polymyxin B (5 μg/ml) and pancuronium (0.3 μg/ml) were added to the bath, a 35 ± 9 percent reduction of twitch tension occurred. Neostigmine (0.1 μg/ml) which previously antagonized pancuronium block, enhanced the block such that by 130 minutes, a 90 percent reduction in twitch tension had occurred (fig 7). Similarly, neostigmine also augmented polymyxin B-tubocurarine block. When polymyxin B (5 μg/ml) and tubocurarine (0.2 μg/ml) were added to the bath, an 82 ± 2 percent depression of twitch tension followed. Although initial antagonism occurred, neostigmine (0.1 μg/ml) augmented the block such that a 100 percent depression of twitch tension occurred by 50 minutes (fig 7).

DISCUSSION

Our results confirm the clinical observations that polymyxin B potentiates the neuromuscular blockade produced by pancuronium and tubocurarine.[5] Polymyxin B (5 μg/ml) did not depress the twitch itself, but markedly shifted the dose-response curves of both pancuronium and tubocurarine to the left. Also, neostigmine augmented rather than antagonized a combined polymyxin B-pancuronium or polymyxin B-tubocurarine neuromusclar block.

Although tubocurarine is one-fifth to one-tenth as potent as pancuronium in most species,[9,10] pancuronium is less potent than tubocurarine in the rat. Consonant with previous studies in the rat diaphragm-phrenic nerve preparation,[10] we found that the ratio between tubocurarine and pancuronium ED_{50} was 0.25 μg/ml/0.8 μg/ml, or 0.31. The *in vitro* results here were performed at 27 C and a pH of 7.1, which are ideal for the rat diaphragm-phrenic nerve preparation. In spite of these low values, the similarity between our results and the clinical observations of Fogdall and Miller[5] suggests that the results of this study apply also to man. Additional *in vivo* studies at higher temperatures and pH are needed for confirmation.

The mechanism by which polymyxin B depresses neuromuscular transmission never has been elucidated. Our results indirectly suggest that polymyxin B does not act by the classic depolarizing, nondepolarizing, or desensitization methods. A depolarizer would be augmented by neostigmine but should antagonize tubocurarine.[11,12] Conversely, a desensitizer or nondepolarizer should augment tubocurarine but be antagonized by neostigmine.[11,12] Clearly, polymyxin B does not fit either classification.

The bactericidal activity of polymyxin B results from an interaction with cell membrane phosphatidylethanolamine, causing an irreversible breakdown in the permeability barriers of the membrane.[13] Such an action on nervous tissue (which has a high phos-

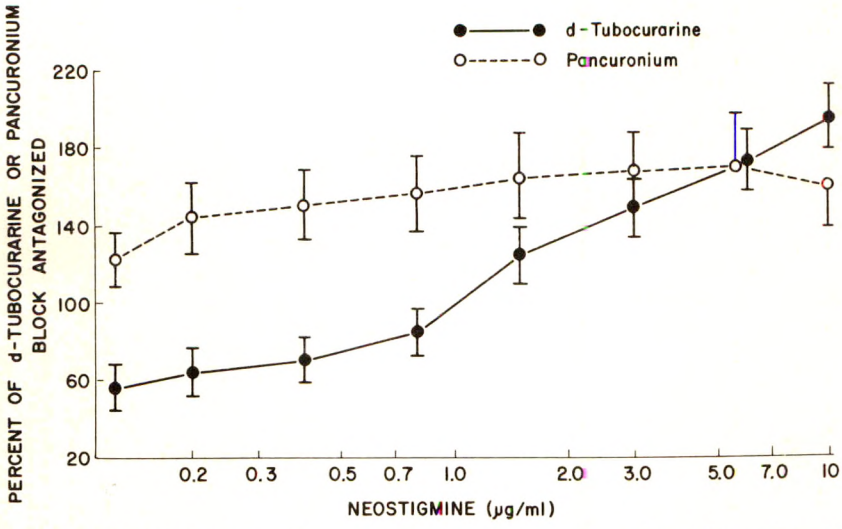

FIG 6. The effect of neostigmine on a pancuronium or tubocurarine-induced depression of twitch tension. The initial pancuronium (1 μg/ml) depression was 84 ± 5% and tubocurarine (0.3 μg/ml) was 73 ± 5%. (N = 6)

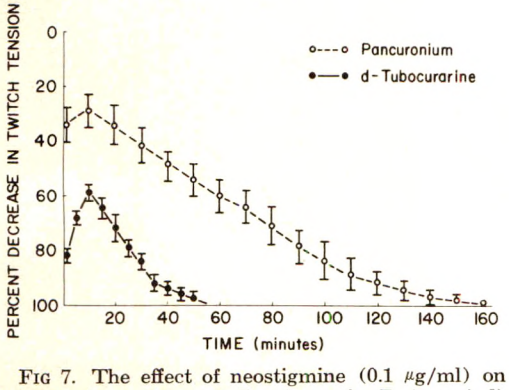

FIG 7. The effect of neostigmine (0.1 μg/ml) on pancuronium (0.3 μg/ml)-polymyxin B (5 μg/ml) induced 35 ± 9% and tubocurarine (0.2 μg/ml)-polymyxin B (5 μg/ml) induced 82 ± 2% depression of twitch tension. (N = 5)

phatidylethanolamine content) or on muscle would reduce their transmembrane potentials. A generalized decrease in transmembrane potential could impair transmitter release, postsynaptic depolarization, and muscle contractility. Obviously, microelectrode studies are required to explore these possibilities.

It is routine practice clinically to administer neostigmine to antagonize a nondepolarizing neuromuscular blockade from pancuronium or tubocurarine. However, in the presence of polymyxin B, neostigmine may actually augment the block, and such a neuromuscular blockade should be allowed to terminate spontaneously with ventilation controlled. Practically, it is difficult to determine how much of the block is from polymyxin B or nondepolarizing relaxant. We administer 2.5 mg/70 kg of neostigmine initially. If the block persists, we do not administer additional neostigmine but allow the block to terminate spontaneously which may take several hours.

AGE, LIVER DISEASE AND DIAZEPAM The separate effects of increasing age or hepatocellular liver disease on diazepam pharmacokinetics were evaluated. In normal patients, following 0.1 mg/kg intravenously or 10 mg orally, the terminal diazepam half-life increased linearly with age from about 20 hours at 20 years to about 90 hours at 80 years. This change was not due to differences in drug metabolizing activity or plasma protein binding but correlated with the initial distribution volume of the drug. Despite the prolonged half-life, the constancy of plasma clearance despite age suggests drug accumulation is no more likely in the elderly than the young patient. Severe liver disease was associated with more than a two-fold increase in diazepam half-life due primarily to reduced plasma clearance (biotransformation) of the drug. Biochemical tests of liver function did not adequately reflect the ability of the diseased liver to metabolize diazepam. Thus, chronic diazepam administration to patients with liver disease might result in cumulative effects. *(Klotz U, Avant GR, Hoyumpa A et al: The effects of age and liver disease on the disposition and elimination of diazepam in adult man. J Clin Invest 55:347-359, 1975)*

Incidence of Prolonged Pain Relief Following Acupuncture

PETER K. Y. LEE, MD*
JEROME H. MODELL, MD†
THORKILD W. ANDERSEN, MD‡
SEGUNDINA A. SAGA, MD§
Gainesville, Florida‖

From March 1973 to December 1974, 2090 electroacupuncture treatments were applied to 533 patients with chronic pain. Of 533 patients, 276 (52%) reported excellent (>75%) pain relief immediately after the last treatment, and 103 (19.3%) still reported excellent pain relief on a 4-week follow-up questionnaire. In March 1975, the authors contacted 87 of these 103 patients. Sixty-three reported that they still had excellent pain relief 3 to 18 months after therapy, 3 patients reported that their pain still was relieved 50%, and 21 patients said their pain had returned to the same intensity as before therapy. Thus, 12% of 533 patients who received acupuncture treatment for chronic pain had a significant degree of pain relief at least 3 months after therapy.

WE PREVIOUSLY reported on 261 patients who received up to 4 consecutive acupuncture treatments for chronic pain.[1] In that study, 133 patients were treated with electrically stimulated needles placed in traditional acupuncture meridians. The remaining 128 patients also received electrical-needle stimulation; however, these had been placed alternately in traditional meridians and in arbitrary locations. We found that 117 patients (54%) reported that their pain was either relieved completely or had decreased in intensity by at least 75% immediately after the 4th treatment. In a 4-week follow-up questionnaire, 47 (18.6%) of the 252 patients who responded still had at least 75% relief from pain.[1] Needle placement did not influence the results in that study. We have continued to study patients using this modality, to determine the incidence of long-term pain relief. The purpose of this report is to identify those patients who received relief from pain for more than 3 months after acupuncture therapy.

METHODS

Between March 1973 and December 1974, 2090 acupuncture treatments were applied to 533 patients suffering from chronic pain. All patients received 3 treatments on successive days and most returned for a 4th treatment. Results of the 4-week follow-up were reported previously in 252 patients (9 patients did not answer the 4-week questionnaire).[1] The remaining 272 patients were treated similarly with needles being placed at traditional meridian points. These have not been reported. Electroacupuncture was performed via 27-gauge hypodermic needles by an electric stimulator with 0.35 ms pulse width; biphasic-capacitor-coupled square wave; pulse rate 10 to 300/sec; and

amplitude 0 to 12 volts variable control. The adjustable controls were set to 200 pulses/sec and 3 volts. The amplitude was further adjusted according to individual tolerance. We did not include patients who were known narcotic addicts or who were in the course of compensation settlement.

Patients interviewed for subjective degree of pain relief by someone not involved in administering the acupuncture were asked to grade the degree of relief as 0, 25, 50, 75, or 100%. Follow-up was in person, by mail, and by telephone.

RESULTS

Of 533 patients, 276 (52%) reported excellent (>75%) pain relief immediately after the last treatment and 103 (19.3%) still reported excellent pain relief on the 4-week posttherapy questionnaire. In March 1975, we contacted 87 of these patients either by a 2nd questionnaire or by telephone. (We were unable to reach the remaining 16 patients.) Of these, 21 patients reported that their pain had returned to the same intensity as before therapy; 63 still had >75% degree of pain relief at 3 to 18 months after therapy; and 3 patients reported their pain still to be relieved 50%. Thus, 12% of the patients contacted had residual pain relief (table 1).

As in our previous study, there was no significant difference in the incidence of pain relief whether the needle placement was in traditional meridian locations or in arbitrary control points.

20 to 40 years	10
Total	66

Of the 66 patients who reported pain relief at least 3 months after therapy, 9 had suffered from pain for less than 1 year before therapy, 35 reportedly suffered from pain from 2 to 8 years, and 22 stated that they had been in pain for at least 10 years (table 2). Thirteen patients had resumed pain medications but in smaller doses than previously used. The remaining 53 patients were no longer taking pain medication. The pretreatment diagnoses of these 66 patients are shown in table 3. Thirty-four patients were male and 32 were female, with a mean age of 61.3 ± 14 years.

DISCUSSION

Neither the mechanism of chronic pain nor the mechanism of acupuncture is fully understood. Thus, treating chronic pain with acupuncture is analogous to a blind person riding a blind horse. Yet, there are numerous testimonials of acupuncture therapy relieving the pain of low back discomfort, arthritis, neuralgia, and headache.[1-6] Of the 533 patients treated in our study, all had been treated previously with drugs and many had been treated surgically. When pain persisted, patients sought acupuncture as an alternative to conventional modes of therapy. While 52% of patients reported at least 75% relief of pain immediately after their last acupuncture treatment, pain returned to many. However, 4 weeks later, 19.3% of patients still had excellent pain relief.

Although the incidence of pain relief fell considerably between the last treatment and the 4-week follow-up, the majority of patients who still had significant pain relief

4 weeks after therapy experienced this relief for at least 3 months. While immediate relief of pain after acupuncture therapy may be a poor indicator of long-term results, our experience suggests that the majority of the patients who have pain relief for at least a month can look forward to long-term effectiveness.

Since there was no difference between those patients who received their therapy along traditional meridians and those who received needles at arbitrarily selected points, we question whether the results of our study represent the results of "acupuncture" or the results of "counterstimulation." Our study was not designed to offer an explanation of the mechanism by which our patients obtained pain relief. However, we did attempt to study the placebo effect by placing needles in other than the traditional meridians. This portion of our study suggests that electrical stimulation at traditional meridians was unimportant. However, if the effectiveness of therapy is due to counterstimulation, this, too, would be produced by the electrical stimulation of the needles in the arbitrary control points. Thus, it was impossible for us to separate a placebo effect from this mechanism.

ACKNOWLEDGMENT

The authors thank Ms. Sherry Kamradt and Mr. Daniel Roberson for their assistance in retrieving the follow-up data.

Circulatory Changes in Patients with Coronary Artery Disease Following Thiamylal-Succinylcholine and Tracheal Intubation

ROBERT K. STOELTING, MD*
CHRISTINE PETERSON, RN†
Indianapolis, Indiana‡

Circulatory responses after thiamylal (4 mg/kg) and succinylcholine (SCh) (2 mg/kg) administration followed by direct laryngoscopy and tracheal intubation were measured in 20 patients before elective aortocoronary vein bypass graft operations. Compared with awake measurements, the mean arterial pressure (MAP) decreased 19 ± 3 torr (mean ± SE) and heart rate (HR) increased 9 ± 3 bpm 1 minute after thiamylal-SCh. MAP was increased 39 ± 4 torr and HR 20 ± 3 bpm above awake levels in response to laryngoscopy and tracheal intubation. Blood pressure and HR returned spontaneously to near awake levels without additional anesthesia within 5 minutes of anesthetic induction. Stroke volume index was decreased significantly after tracheal intubation but cardiac index was not altered.

The authors conclude that thiamylal-SCh followed by tracheal intubation is an acceptable anesthetic induction sequence for patients without evidence of left ventricular heart failure who require anesthesia for elective coronary artery revascularization.

A PRIMARY goal in anesthetic management of the patient with coronary artery disease is to minimize alterations in myocardial O_2 requirements and maintenance of coronary blood flow.[1] Barbiturate anesthetic induction may produce decreases in blood pressure that could impair myocardial O_2 delivery, while increased myocardial O_2 needs might result from increased blood pressure and heart rate (HR)[2] during direct laryngoscopy and tracheal intubation. If excessive or persistent, these circulatory changes could adversely alter the ratio of myocardial O_2 delivery to consumption, especially in patients with stenotic coronary arteries.

This study reports the duration and magnitude of circulatory changes after rapid IV thiamylal administration followed by succinylcholine (SCh), direct laryngoscopy, and tracheal intubation in patients with coronary artery atherosclerosis.

METHODS

Twenty adult patients (53 ± 2 years, 78 ± 3 kg, mean ± SE) were studied in the supine position before elective aortocoronary vein bypass graft operations. No patient was included in the study if left ventricular heart failure was considered present. Average left ventricular end-diastolic pressures and cardiac indices (CI) at preoperative cardiac catheterization were 8.6 ± 1.1 torr and 3.1 ± 0.3 L/min/sq m, respectively. No patient had received propranolol for at least 24 hours. Preanesthetic medication was with IM morphine (8 to 15 mg) and scopolamine (0.4 to 0.6 mg) about 60 minutes before arrival in the operating room.

A radial artery and internal jugular vein were cannulated and pressures recorded continuously, as was lead 2 of the ECG. After administering 100% O_2 by face mask for 3 minutes, mean arterial pressure

Paper received: 5/27/75
Accepted for publication: 7/7/75

(MAP), HR, and cardiac output (indocyanine green dye and Beckman Cardiodensitometer) were measured. Stroke volume index (SVI), systemic vascular resistance (SVR), and CI were calculated. d-Tubocurarine (40 mcg/kg) was then administered IV, followed 3 minutes later by 4 mg/kg of thiamylal and then by 2 mg/kg of SCh. All drugs were injected rapidly into a forearm vein through a 5 cm Teflon catheter, followed by 5 ml of flush solution to insure entrance into the circulation.

Ventilation was manually controlled via face mask within 15 seconds following thiamylal-SCh. One minute after thiamylal-SCh administration, laryngoscopy with a straight laryngoscope blade was started and the trachea intubated with a cuffed (low-pressure) orotracheal tube. Just before tracheal intubation, 2 mg/kg of 4% lidocaine was sprayed into the larynx and trachea by a Laryngotracheal Anesthesia Kit. Following intubation, ventilation was controlled with a volume ventilator delivering O_2 until 5 minutes following the thiamylal-SCh. Cardiac output measurements were repeated 3 minutes after anesthetic induction. Data were analyzed by Student's *t*-test, with $p<0.05$ considered significant.

RESULTS

Circulatory responses to anesthetic induction, direct laryngoscopy and tracheal intubation are summarized in table 1. The maximum MAP decrease compared with the awake value was 27 ± 5 torr, 43 ± 3 seconds following thiamylal-SCh. MAP was not less than 60 torr in any patient. One minute after thiamylal-SCh administration, MAP was 19 ± 3 torr less than the awake value and HR was increased 9 ± 3 bpm.

Direct laryngoscopy for tracheal intubation was started 1 minute after thiamylal-SCh administration and lasted 35 ± 3 seconds. This stimulation was associated with a maximum MAP increase of 39 ± 4 torr 5 seconds after completion of laryngoscopy, and by 2 minutes after anesthetic induction, the MAP was decreasing. HR was increased 20±3 bpm above awake levels after tracheal intubation. SVI was decreased ($p<0.05$) after anesthetic induction and tracheal intubation but CI was not significantly altered. MAP and HR decreased after tracheal intubation without additional anesthesia and 5 minutes after thiamylal-SCh were not significantly different from awake values. ST-segment changes, suggestive of myocardial ischemia, were not observed on lead 2 of the ECG in any patient during the 5 minutes after anesthetic induction.

DISCUSSION

Alterations in MAP and HR following thiamylal-SCh induction and tracheal intubation were transient. Therefore, the likelihood of decreased O_2 delivery during reduced perfusion pressure or elevated myocardial O_2 requirements due to increased MAP and HR in response to direct laryngoscopy and tracheal intubation should be minimal. Indeed, ECG evidence of myocardial ischemia was not observed in any patient during this anesthetic induction sequence. Nevertheless, a multiple lead ECG might have revealed ischemic changes that were not apparent from monitoring only lead 2.

The magnitude of MAP and HR changes after thiamylal-SCh administration to patients with coronary artery disease was similar to that in patients without known coronary artery disease but anesthetized in an

*$p < 0.05$. Coronary artery disease compared with normal.

identical manner (table 2).[3] However, the awake MAP and maximum MAP achieved in response to direct laryngoscopy and tracheal intubation were significantly greater in patients with coronary artery disease.

Impaired left ventricular contractility due to coronary artery disease and/or beta-adrenergic blockade from propranolol might influence the circulatory response to anesthetic induction and subsequent tracheal intubation. Preoperative ventriculograms revealed areas of left ventricular dyskinesis in 4 of our 20 patients. However, circulatory responses were similar to those seen in patients without detectable areas of impaired left ventricular contractility, and the data were pooled for all 20 patients.

With respect to beta-adrenergic blockade, Prys-Roberts and coworkers[4] reported reduced circulatory responses to anesthetic induction (thiopental or Althesin), laryngoscopy, and tracheal intubation in hypertensive patients receiving practolol. However, discontinuing propranolol 24 hours preoperatively, combined with the brief plasma half-life of the drug,[5] makes it unlikely that beta-adrenergic blockade contributed to the circulatory responses observed in our patients.

We conclude that thiamylal-SCh anesthetic induction followed by tracheal intubation was not associated with persistent changes in MAP or HR in patients with coronary artery disease. Furthermore, the magnitude of these changes was similar to that previously demonstrated in patients without known coronary artery disease. Therefore, this would seem an acceptable anesthetic induction sequence for patients requiring anesthesia for elective coronary artery revascularization operations. It must be emphasized that circulatory responses could be different in hypovolemic patients or those with signs of left ventricular heart failure.

Failure to Induce Hepatic Pathology in Animals Sensitized to a Halothane Metabolite and Subsequently Challenged with Halothane

J. G. REVES, MD*
LINTON E. McCRACKEN, JR., MD†
Bethesda, Maryland‡

The results of this animal study confirm the induction of delayed hypersensitivity to a halothane metabolite, but the sensitization does not cause hepatic damage on subsequent halothane exposures. Before the hypothesis that hepatic necrosis following halothane has an immunologic basis can be accepted or rejected, more critical studies with different approaches must be made.

POSTOPERATIVE liver dysfunction has been attributed to halogenated anesthetics in a small number of patients. It is postulated in certain susceptible individuals that the anesthetic, or one of its metabolites, acts as a hapten, causing a hypersensitivity reaction that ultimately destroys the liver.[1-3] Other theories that could explain hepatic destruction have been recently reviewed,[4] but hypersensitivity has been the most widely accepted, primarily because of the apparent exacerbation of two cases of hepatitis in anesthesiologists challenged with halothane.[5,6]

The halogenated anesthetics are small and essentially unreactive compounds. The molecular weight of halothane, 197, is considerably less than the smallest immunogenic synthetic molecules, which average 4000 to 5000.[7] Therefore, if there is an immunologic basis for halogenated-anesthetic-induced hepatic pathology, it is most likely the result of the formation of a metabolite that acts as a hapten and combines with autologous protein to form an immunogenic hapten carrier complex. It is unlikely that the inert halothane molecule can itself form a hapten carrier complex.

Trifluoroacetic acid (TFA) is a metabolite of three halogenated anesthetic agents:

halothane,[8] fluroxene,[9] and isoflurane.[10] Unlike the parent compounds, the products of biotransformation are concentrated in the liver, are chemically reactive, and are capable of forming hapten carrier complexes that could initiate hypersensitivity reactions in the liver. Mathieu's group has demonstrated delayed[11,12] and humoral[13] responses to trifluoroacetylated autologous serum protein in guinea pigs.

Although hypersensitivity can be induced to trifluoroacetylated albumin, it does not mean that this hapten carrier complex is responsible for liver injury following use of the parent compounds. Many diverse compounds complexed to carrier proteins will induce delayed hypersensitivity. The purpose of the experiments reported here was to induce hypersensitivity to trifluoroacetylated homologous serum protein, challenge immunized animals with halothane, and correlate hepatic pathology with the degree of hypersensitivity. Inherent in the study is the question whether the biotransformation product, TFA, complexed to homologous serum protein, is an appropriate antigenic structure to create experimental liver necrosis.

METHODS

Animals.—Twenty-four NMRI(H)* and 53 Dunkin Hartley† guinea pigs of both sexes weighing 350 to 550 gm, fed commercial guinea pig diet and given water containing 2 mg/ml ascorbic acid, were used.

Preparation of Antigens.—Trifluoroacetate was conjugated to guinea pig albumin (GPA) and to human serum albumin (HA) by the method of Goldberger and Anfinsen.[14] Primary reagents were ethyl thioltrifluoroacetate (Pierce Chemical Company, Rockford, Illinois) and human and guinea pig serum albumin (Sigma Company, St. Louis, Missouri).

Samples of the lyophilized trifluoroacetylated protein complexes were sent for fluorine analysis to Schwarzkopf Microanalytical Laboratories, Woodside, New York, and revealed a fluorine content of 4.27% (TFA-GPA) and 4.1% (TFA-HA). The calculated molar ratios were 163 moles fluorine/mole human albumin and 166 moles fluorine/mole guinea pig albumin.

Immunization.—The guinea pigs were divided into three groups. One group received TFA-GPA in doses of 25 to 200 mgm, partially dissolved in physiologic saline solution and then emulsified in complete Freund's adjuvant (CFA) (Difco Laboratory, Detroit, Michigan) which contained 1 mg *Mycobacterium butyricum* per ml of oil. The second group received complete Freund's adjuvant, and the total immunizing dose was divided into four 0.1-ml aliquots, which were injected subcutaneously into each footpad. The third group received similar volumes of saline solution and served as an immunization control.

Skin Tests.—Three weeks after immunization, the flanks were shaved and intradermal injections of antigens administered in 0.1 ml solution of physiologic saline. The antigens tested were: saline, as a nonreactive control; GPA (10 μgm) and HA (10 μgm), as albumin controls; tuberculin purified protein (PPD) (0.1 μgm) to show delayed hypersensitivity response to the CFA; TFA-HA (10 μgm) to test for carrier specificity; and TFA-GPA (10 μgm)—the immunizing compound.

Reactions were observed at 2, 4, 6, 24, and 48 hours and were recorded as either immediate or delayed. Immediate skin reactions were graded at 2, 4, and 6 hours after skin testing based on the following scale:

1—slight edema
2—severe hemorrhage
3—severe edema with necrosis and hemorrhage
4—marked hemorrhage and necrosis

Delayed skin reactions were graded according to the diameter of erythema and induration at 24 and 48 hours after skin testing. Biopsies of the cutaneous reactions were made in three animals 48 hours after testing. The tissue was fixed in 10% formalin buffer and later stained with hematoxylin-eosin (H & E) for microscopic examination.

Halothane Challenge.—Each major group was divided into two subgroups, H and O. Subgroup O was exposed to 100% O_2 and H was exposed to 1% halothane in O_2. The halothane was delivered by a calibrated Fluotec® Mark 2 vaporizer with a 4 L/min O_2 inflow for a period of 2 hours, 3 days after skin testing. The gases were delivered into a 9600 ml clear-plastic box containing two or three guinea pigs. In a series of subsequent experiments, this technic was found to lightly anesthetize the animals but not significantly depress respiration, although hypotension results.[15]

*Naval Medical Research Institute Hartley Strain.
†Perfection breeders.

Liver Study.—The animals were sacrificed five days after halothane exposure. They were stunned by a blow to the head and exsanguinated by cardiac puncture. The liver was examined grossly for any abnormalities, and representative, 5-mm slices from each lobe were placed in 10% formalin buffer. The fixed tissue was then sectioned and stained with H & E for microscopic examination and the degree of fatty change and necrosis scored in the following manner:

1. *Hepatic Necrosis.*—The number of foci of hepatic necrosis were counted on 10 different 40x magnification fields. The fields from each slide were systematically scanned, so that no field was counted more than once. The mean number of foci of necrosis per field was calculated after examining at least three different liver sections from various hepatic sites.

2. *Fatty Changes.*—Fatty changes were scored on a scale of 0 to 4:

0—Less than 20% of all cell cytoplasm contained less than 25% fat.

1—20 to 40% of all cell cytoplasm contained less than 25% fat.

2—40 to 60% of all cell cytoplasm contained 25 to 50% fat.

3—60 to 80% of all cell cytoplasm contained 50 to 75% fat.

4—Over 80% of all cell cytoplasm contained over 75% fat.

All slides were coded so that the observer was unaware of the animal's grouping and treatment.

Statistical Analysis.—Mean, standard deviation, and standard error were calculated on all observations. Mean skin-test scores were compared by analysis of variance. Fatty change and hepatic necrosis between groups was compared by unpaired t-test. Differences between means were considered significant if the calculated p value was 0.05 or less.

RESULTS

Skin Tests.—The results of cutaneous antigen testing at 2, 4, and 6 hours revealed no positive skin reactions to saline, GPA, and HA in all groups. There were occasional positive reactions resulting in erythema and edema in some animals in all groups in response to PPD, TFA-HA, and TFA-GPA. The responses were not significantly different at the 5% confidence level among groups. Responses at 24 hours are shown in table 1. The number of positive responses to TFA-GPA were significantly ($p<0.05$) greater in group I than groups II and III.

Figure 1 demonstrates a typical cutaneous response to TFA-GPA at 24 hours in a group-I animal. Of importance is the highly significant ($p<0.0005$) difference in response of group I to TFA-GPA (23/48) compared to TFA-HA (1/39), a manifestation of carrier specificity. The positive skin reactions to PPD were significantly greater in groups I and II than in group III, which was not immunized with complete Freund's adjuvant. Responses at 48 hours were similar to those at 24 hours, but only responses to TFA-GPA and PPD were significantly greater than other antigens in group I as compared with group III. The degree of response to all antigens at 48 hours was less than at 24 hours.

Liver Studies.—There were no differences in degree of fatty metamorphosis among groups or within subgroups exposed to halothane and not exposed to halothane. Table 2 shows results of fatty change scores in all groups. Small foci of hepatic necrosis were found in many animals, and figure 2 shows

TABLE 1
Number of Positive Cutaneous Reactions 24 Hours After Testing

Antigen	Saline	GPA	HA	TFA-GPA	TFA-HA	PPD
Group I	0/48	10/48	0/47 (1 not tested)	23/48	1/39 (9 not tested)	35/48
Group II	0/11	0/11	0/11	0/11	0/11	4/11
Group III	0/6	0/6	0/6	0/6	0/6	0/6

Responses greater than 5 mm of erythema and induration are positive. HA = human albumin; TFA-GPA = trifluoroacetylated guinea pig albumin; TFA-HA = trifluoroacetylated human albumin. Group I immunized with trifluoroacetylated guinea pig albumin (TFA-GPA) in complete Freund's adjuvant (CFA). Group II immunized with CFA. Group III no immunization.

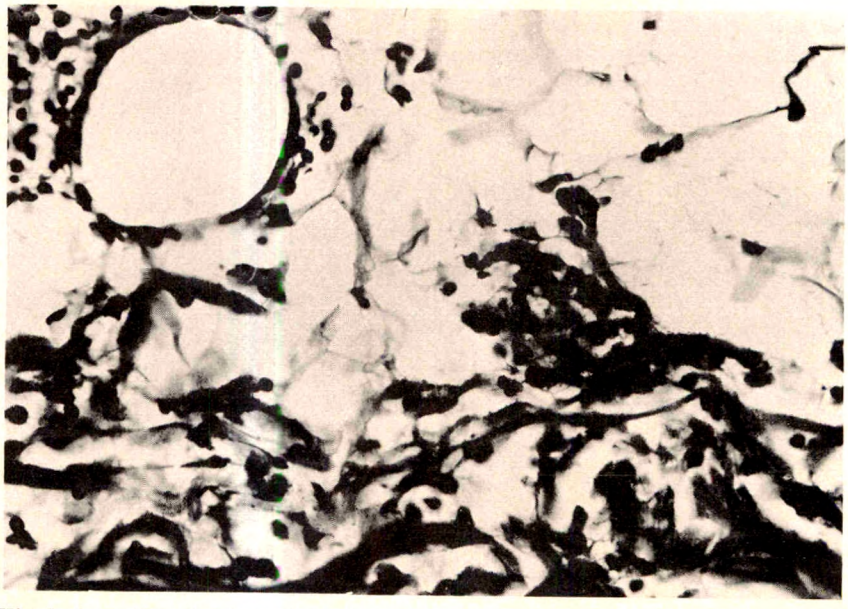

FIG 1. Histologic section showing cutaneous reaction from a guinea pig immunized with 100 μgm trifluoroacetylated guinea pig albumin (TFA-GPA) and tested 3 weeks later with the same complex in saline. The predominant cellular infiltrate is mononuclear and edema is seen in the connective tissue. H & E x 900.

TABLE 2

Scores* of Fatty Changes (± SE) in Guinea Pig Livers

Exposure	Group I	Group II	Group III
Halothane	0.98 ± 0.22 (28)	0.58 ± 0.33 (6)	1.17 ± 0.17 (6)
Oxygen	1.12 ± 0.34 (13)	0.60 ± 0.40 (5)	1.83 ± 0.63 (6)

*Scored 0-4 in increasing severity (see text). Group I immunized with trifluoroacetylated guinea pig albumin (TFA-GPA) in complete Freund's adjuvant (CFA). Group II immunized with CFA. Group III no immunization. Parentheses indicate number of animals in each group.

a representative lesion. Results of the mean number of such foci per 40x microscopic field are presented in table 3 for each group. The foci of necrosis were midzonal and resembled granulomatous areas.

The number of foci was not statistically different among groups or within groups between the halothane-challenged animals and the O_2 controls. There was no discernible difference in type or location of the foci of necrosis in all groups. No areas of massive acute hemorrhagic or coagulative necrosis were observed, nor were mononuclear cellular infiltrates present.

To correlate the degree of delayed hypersensitivity to incidence of focal hepatic necrosis in group I, the 24-hour skin test responses were plotted for each animal with its number of hepatic necrosis foci (fig 3). Using least-square fit analysis, the slopes of group 1-O and group 1-H did not differ from 0 or from each other at the 5% significance level. Therefore, there is no correlation between the degree of skin reaction and number of necrotic foci.

DISCUSSION

Halothane-induced liver injury has been attributed to a hypersensitivity reaction involving autoimmune hepatic destruction. The evidence for this thesis is unconvincing, being based primarily on clinical observations of nonspecific criteria of immune reactions such as fever, rashes, arthralgia, eosinophilia, and an increased incidence of necrosis on repeat exposure to halothane. The most cogent arguments supporting a hypersensitivity process are the two cases of recurring hepatitis in anesthesiologists that followed provocative challenges.[5,6] The history in one of these cases is consistent

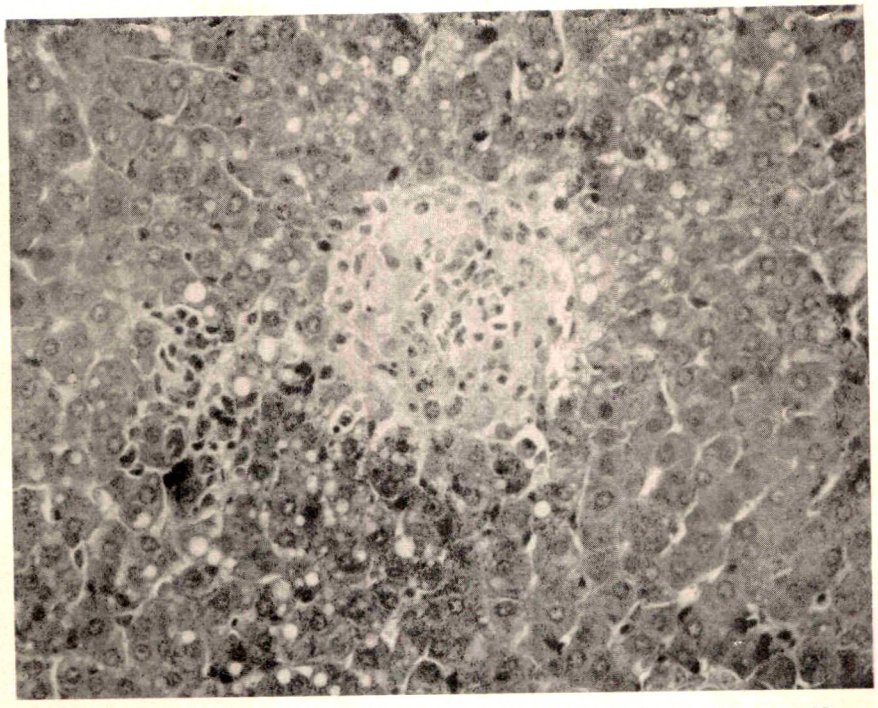

FIG 2. Histologic midzonal section of liver from a guinea pig immunized with 100 μgm trifluoroacetylated guinea pig albumin exposed to 1% halothane/O_2 after 23 days. In the center of normal liver parenchyma is a small focus of coagulation necrosis, distinguished by pyknotic nuclei and homogenous cytoplasm. This lesion is typical of those found in many animals of all groups. H & E x 400.

TABLE 3

Mean Number* (± SE) of Foci of Hepatic Necrosis in Guinea Pig Livers

Exposure	Group I	Group II	Group III
Halothane	1.28 ± 0.81 (28)	0.15 ± 0.10 (6)	1.85 ± 0.48 (6)
Oxygen	0.91 ± 0.24 (13)	0.94 ± 0.61 (5)	0.57 ± 0.37 (6)

*Number of foci of necrosis observed in 40x microscope field. Group I immunized with trifluoroacetylated guinea pig albumin (TFA-GPA) in complete Freund's adjuvant (CFA). Group II immunized to CFA. Group III no immunization. Parentheses indicate number of animals in each group.

with recurrent hepatitis, and has been challenged for this reason.[16]

Although initial reports employing in-vitro lymphocyte stimulation[17] and leukocyte migration methods[18] to detect patients with halothane hepatitis seemed to support a delayed hypersensitivity foundation for the disease, these could not be reproduced.[19,20] The test antigens were halothane or sonicated halothane in serum, and as previously discussed, it is doubtful that this is the appropriate antigen. There have been no well-documented clinical studies demonstrating an immunologic basis as a mechanism for halothane hepatitis.

Since the halothane molecule itself is an unlikely antigen, investigators have postulated that the reactive metabolite, TFA, may complex with autologous protein to form a hapten carrier complex. Experiments have demonstrated that trifluoroacetylated autologous protein can induce hypersensitivity reaction in laboratory animals. Both delayed hypersensitivity mediated by the thymus-lymphocyte (T-cell)[11,12] and immediate reaction involving specific antibody formation[13] have been induced against this hapten carrier complex. The fact that hypersensitivity to a drug metabolite complexed to protein can be induced does not mean

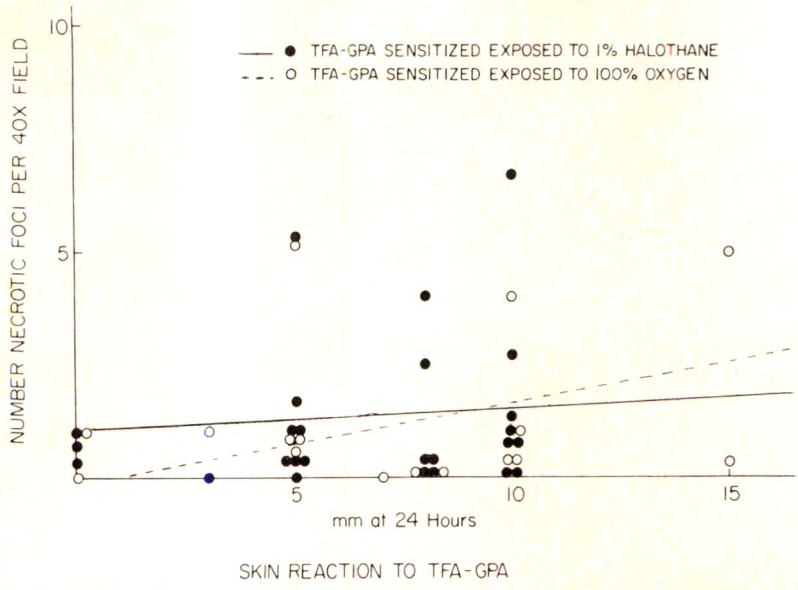

FIG 3. Relation between incidence of foci of necrosis and diameter of skin reaction in guinea pigs immunized with trifluoroacetylated guinea pig albumin. Data from animals exposed to 1% halothane are plotted as closed circles; points from animals exposed to 100% O_2 are shown as open circles. The solid line and dashed line represent the least-square fit of the data derived from halothane-challenged and from O_2-challenged animals, respectively. The slopes of the two groups do not differ significantly from zero or each other.

that this hapten carrier complex causes autoimmune liver destruction.

The data are consistent with those of Mathieu's groups in demonstrating that a delayed hypersensitivity can be induced to TFA-GPA.[11,12] The skin tests show delayed hypersensitivity mediated responses to the antigen. This interpretation is based on the facts that the peak response occurred at 24 hours and that the cellular infiltrate in the biopsied lesions were primarily mononuclear. Also, in support of a delayed response, is the fact that the positive skin test responses were carrier specific, ie, the hapten, TFA, complexed to the autologous carrier protein, GPA, did evoke positive responses, but the same hapten, TFA, complexed to another carrier, heterologous HA, did not cause positive responses in animals sensitized to TFA-GPA.

The second part of the present study addressed the question of hepatic pathology following halothane challenge in animals sensitized to TFA. The data indicate that there is no difference in the number of foci of necrosis found in all groups, whether sensitized to TFA or not. Further, on correlating the degree of delayed hypersensitivity demonstrated by skin test with the incidence of necrosis in the halothane-challenged animals and control O_2-exposed animals of group I, there was no positive correlation and no difference between groups I-H and I-O. Thus it is concluded that sensitization to TFA-GPA followed by halothane challenge does not cause increased hepatic necrosis in the guinea pig.

The presence of foci of hepatic necrosis in all groups (experimental—group I, and controls—groups II and III), as well as the type, degree, and location of necrosis, was similar among all groups. The cause of these lesions is unknown, but the granulomatous nature suggests a subclinical infectious process. Spontaneous lesions in guinea-pig colonies have been reported following infectious processes.[21] Incidence of hepatic fatty changes did not differ among groups or within subgroups. This finding is somewhat at variance with a previous report in which fatty changes were increased in halothane-treated animals compared to O_2 controls.[22] It is impossible to explain this discrepancy, but it should be noted that the present study contains more animals, and the differences between groups in the former study are small.

It would appear from the data that sensitization to a halothane metabolite with subsequent halothane challenge does not

cause hepatic injury. These findings are similar to those reported by Mathieu and coworkers,[23] who sensitized animals to TFA-GPA and demonstrated antibodies (immediate hypersensitivity) against the antigen, but failed to induce increased hepatic pathology after halothane challenge to the animals.

It is important to comment on several considerations about the present experimental model. The guinea pig was chosen because of the report that it was a suitable model for experimental halothane hepatitis[24] and the previous immunologic work in this animal.[11-13] The finding of hepatic lesions in control animals, and the question of whether the guinea pig significantly differs in metabolic or immunologic responses from the human, are valid. The halothane dosage and duration are open to criticism because of the uncertainty of the effects of induced hypotension on the liver;[15,16] however, similar liver pathology was found in O_2 controls, suggesting that decreased perfusion pressure was not responsible for the lesions encountered.

Trifluoroacetic acid is not the sole metabolite of halothane; therefore, other compounds closely related could be the hapten. A reactive intermediary compound, trifluoroacetaldehyde, as recently demonstrated by Van Dyke and Gandolfi to be bound to liver lipoprotein after halothane exposure, is one such compound.[25] Trifluoroacetic acid is a reactive compound and, being by far the largest metabolic product of halothane, would appear the most appropriate to use. However, it is possible that subtle chemical changes among halothane metabolites could alter the immunologic significance of the compounds by alterations in stoichiometric configuration.

A final comment on the present model is the selection of the carrier protein, homologous guinea pig albumin. An alternative carrier protein is autologous liver lipoprotein. Liver lipoprotein normally complexes fatty acids produced in the liver.[26] Two well characterized proteins[27] from cytoplastic fractions of liver have exhibited liver-specific antigenicity. A membrane lipoprotein has been found to inhibit normal migration of leukocytes from patients with autoimmune liver disease (active chronic hepatitis and primary biliary cirrhosis).[28] It is conceivable that TFA or another hapten complexed to this liver-specific lipoprotein might form a hapten carrier complex that constitutes a basis for halothane-induced hypersensitivity and hepatic necrosis.

ACKNOWLEDGMENT

The authors are indebted to Dr. E. Dowdy for her encouragement and aid during the initial experiments and thank Drs. A. Lawton and M. Cooper, Department of Immunology, Birmingham, for their assistance in designing the study. We also thank Drs. R. Tobey, T. Ahmed, and Vanier, Naval Medical Research Institute, for their review of the manuscript, and Ms Linda Porter for her clerical help.

FLUROXENE TOXICITY Repeated exposures to fluroxene result in high mortality in all animals species studied to date. Man metabolizes fluroxene differently and toxicity after fluroxene is rare but when it does occur may be associated with a history of drug ingestion capable of producing enzyme induction. The influence of phenobarbital pretreatment on fluroxene toxicity was studied in monkeys since these animals resemble man in biotransformation of xenobiotics. Unlike other animals species, monkeys survived repeated exposures to fluroxene without overt organ toxicity. In contrast, all animals treated with phenobarbital died during fluroxene anesthesia manifesting arterial hypotension and pulmonary edema. It was speculated that phenobarbital increased production of fluroxene metabolites, including the highly toxic trifluoroethanol. The monkey may serve as an animal model to evaluate drug toxicity with and without enzyme induction prior to use in man. *(Munson ES, Malagodi MH, Shields RP et al: Fluroxene toxicity induced by phenobarbital. Atypical Pseudocholinesterase: A Clinical Report

ERWIN LEAR, MD*‖
CASSIM JADWAT, MD†
LUCY BOUGH, MD‡
PAZ FERNANDEZ, MD§
Jamaica, New York‖

The safe conduct of anesthesia demands careful evaluation of the previous experience of patients under anesthesia and surgical operation, as well as that of their families. Untoward responses that may recur with subsequent anesthetic procedures should be documented and patients informed, as the need dictates. Two cases of prolonged apnea following single intubating doses of succinylcholine could not have been predicted by the patient's preanesthetic history. As a result of these problems, the authors recommend more careful preanesthetic history-taking with reference to patients' prior anesthetic experiences.

THE safe anesthetic management of patients depends on the orderly logic of the anesthesiologist as he sorts and analyzes data input from the unconscious patient. It would thus seem incumbent upon the anesthesiologist to study patients carefully when they exhibit unusual responses to the usual conduct of anesthesia.

Prolonged apnea associated with IV drip succinylcholine during operation was reported during the early clinical trials with this drug. While the catabolism of succinylcholine was linked to the enzyme plasma cholinesterase (pseudocholinesterase), other factors have been implicated in a casual relationship to prolonged apnea. It was also noted on occasion that patients experienced significant periods of apnea after receiving a single intubating dose of succinylcholine.

Within the past year, 2 cases of prolonged apnea following single intubating doses of succinylcholine have occurred in one of our hospitals. In each instance, there was no preoperative clue to forewarn us.

CASE PRESENTATIONS

Case 1.—The patient was a 2½-year-old boy weighing 10 kg, admitted for tonsillectomy, adenoidectomy, myringotomy, and bilateral tubal implants. Preoperative physical examination revealed enlarged tonsils and bilateral otitis media but was otherwise noncontributory. The preoperative history as set forth on the chart also was noncontributory except to verify otitis media. No parent was available for further questioning during preanesthesia rounds.

Premedication consisted of 40 mg of pentobarbital and 0.2 mg of atropine IM approximately 1 hour before scheduled operation. The patient arrived in the operating

room with a pulse of 140/min, calm and afebrile.

Anesthesia was induced with halothane-N_2O-O_2, 8 L/min, by face mask in a nonrebreathing system. Induction was smooth and 20 mg of succinylcholine was administered IM approximately 8 minutes after induction. Intubation was easily accomplished, ventilation was controlled, and the operation began.

During the 20-minute surgical procedure, vital signs were stable, but the patient remained apneic. Pupils were in midposition and reacted to light. Electrical stimulation of the ulnar nerve produced a minimal twitch response with no tetanus and no posttetanic facilitation; a depolarizing block was apparently still in effect. Blood was drawn for plasma pseudocholinesterase studies. Respiration was still controlled and the endotracheal tube was in place.

The first spontaneous respiratory efforts were observed 3 hours from the time of succinylcholine injection. Another hour passed before tidal volume reached 100 ml, at which time electrical stimulation of the ulnar nerve resulted in an improved twitch response and tetanic response with no posttetanic facilitation. The patient was extubated and discharged to the pediatric floor.

The likelihood of an atypical pseudocholinesterase syndrome was explained to the patient's father, who only then related the following information to us. He had undergone an operation approximately 5 years before and was told that he "took a long time in waking up." Furthermore, the father's mother had a similar experience over 10 years before and consequently was now refusing to undergo biliary surgery out of fear from her prior experience. We could not obtain further information regarding the patient's father or paternal grandmother.

Laboratory results received after the patient's discharge revealed a plasma benzoylcholine rate of 18.8 μmol/hr/ml and a dibucaine number of 21.3 (table), showing the patient to be positive for homozygous atypical pseudocholinesterase. The family, family physician, and surgeon were so notified by mail and family testing recommended. They were advised to notify any physician, surgeon, and anesthesiologist in the future of our findings. The family was also advised orally against exposure to insecticides; this was confirmed in writing to include other cholinesterase inhibitors.

Case 2.—The patient was a 52-year-old man weighing 79.9 kg, admitted for repair of a left inguinal hernia. Preoperative physical findings were within normal limits except for his presenting complaint and a right inguinal scar. An ECG was within normal limits. Chest x-ray revealed increased interstitial marking consistent with old granulomatous disease. Past history revealed only that he had undergone a right inguinal herniorrhaphy about 12 years before.

Premedication consisted of 50 mg of meperidine and 0.4 mg of atropine, IM, approximately 1¼ hours before induction of anesthesia. The patient arrived in the operating room calm and awake, with vital signs intact.

Anesthesia was induced with thiopental slowly IV in a 2.5% solution; total dose 300 mg. The patient was oxygenated and 100 mg of succinylcholine administered IV to facilitate intubation, which was accomplished without difficulty. Anesthesia was maintained by halothane-N_2O-O_2 in a semiclosed system.

Intraoperative ventilation was controlled during a 1-hour procedure; no additional relaxant was required. Patient remained apneic for 30 minutes after operation, during which time ventilation was still manually controlled. He began to strain against the endotracheal tube, which was then removed to prevent disruption of the hernia repair. His shallow respiratory efforts were easily assisted via face mask, oral airway, and room air.

The patient was now fully alert but complained of difficulty in spontaneous breathing. His hand grip was noted to be weak

and he was unable to raise his head. Blood-gas analysis revealed the following: Pao_2 98, $Paco_2$ 46, HCO_3^- 24, and pH 7.34. An additional blood sample was drawn for pseudocholinesterase study.

The patient's subsequent course was uneventful. Prior to discharge on the 6th postoperative day, he recalled "spending a long time" in the recovery room following his previous operation of 12 years before. He was then informed of our suspicions and the situation was explained to him, with instructions to await a final written report.

Laboratory findings revealed a plasma benzoylcholine rate of 27.1 μmol/hr/ml and a dibucaine number of 24.9 (table). He was positive for homozygous atypical pseudocholinesterase. As in the previously described case, the significance of these findings was reported to the patient by mail, family test was urged, and others concerned were notified.

DISCUSSION

Prolonged apnea following IV drip succinylcholine for surgical relaxation was observed and studied by early investigators.[1,2] While the role of plasma pseudocholinesterase in the catabolism of succinylcholine was recognized, early investigators were intrigued by the association of bowel surgery and prolonged apnea.

Borders and coworkers[3] took a broader approach to the problem, and in 1955 carried out a well-planned study which determined a multiplicity of events that could contribute to prolonged apnea following IV-drip succinylcholine. Recognizing the degradation of succinylcholine by plasma pseudocholinesterase to be a key factor, these investigators studied a series of hospitalized surgical patients and nonhospitalized individuals; there was no significant difference in their plasma enzyme levels. They identified other events leading to prolonged apnea as controlled ventilation (relative hyperventilation); concomitant use of cyclopropane, which in itself depresses the respiratory centers; and too heavy reliance on muscle relaxant, thus overwhelming the myoneural junction.

One year later, Foldes and associates[4] noted that low pseudocholinesterase levels, as found in patients with liver disease, did not usually cause prolonged apnea. They postulated that such apnea resulted from change in the nature of the neuromuscular block "from a depolarizing to a nondepolarizing" action, which could then be terminated by neostigmine.

Prolonged apnea following single intubating doses of succinylcholine was still not adequately explained, however, until Kalow[5] shed light on the subject with data on the presence of abnormal (atypical) plasma pseudocholinesterase as a genetic variant.

In the patient with the genetic variant of plasma pseudocholinesterase, a single bolus of succinylcholine is only partially hydrolyzed in the blood stream, so that a relatively large percentage of the administered dose overwhelms the myoneural junction. As a consequence, the removal of succinylcholine by diffusion away from the myoneural junction is prolonged. The result is a persistent apnea well beyond the usual 2 to 4 minutes in the patient with typical (normal) pseudocholinesterase enzyme.

This situation is not analogous to that in which the block is thought to shift from "depolarizing" to "nondepolarizing." These patients are unusually sensitive to anticholinesterase agents; hence, early use of neostigmine would in fact accentuate the block. Indeed, our first case revealed no shift in type of block when tested electronically, and the use of neostigmine would only have prolonged his problem.

Kalow noted that the abnormal or atypical pseudocholinesterase could be distinguished from the normal enzyme by comparing the degree of inhibition of dibucaine under controlled conditions. Typical (or normal) pseudocholinesterase activity is inhibited approximately 80% by dibucaine; atypical (or abnormal) pseudocholinesterase is inhibited approximately 20% by dibucaine, while some patient samples fall between the two extremes.

For more detailed understanding of the additional genetic variations and the diagnostic technics for identifying these variants, the reader is referred to the reports of Harris,[6,7] Neitlick,[8] Prince,[9] and Kalow.[10]

Of clinical importance is the diminished catabolism of other cholinesterase inhibitors experienced by patients with homozygous atypical pseudocholinesterase. They are at great risk from many organic insecticides as well as from procaine, physostigmine, ecothiopate iodide (eye drops),[11] hexamethonium fluoride, diisopropyl flurophosphate, and related compounds.

The point has been raised that since alkaline hydrolysis is an alternative route in

the degradation of succinylcholine, the administration of bicarbonate should be of value in terminating prolonged apnea. Since the problem is relegated primarily to the succinylcholine at the myoneural junction, the amount of IV bicarbonate required would probably have to be extremely large, creating additional problems for the patient. Kalow[10] points out that less than 5%/hr of succinylcholine present will be deactivated by alkaline hydrolysis. He writes:

"Interest in the subject has been initiated by the special medical and legal problems that arise when a hereditary defect causes a patient to be harmed by a conventional application of a conventional drug."

It would appear incumbent on anesthesiologists to document carefully all cases of prolonged apnea following single intubating doses of succinylcholine, to rule out the inherited metabolic defect. Only then can patients receive intelligent instructions regarding future operations and anesthesia. Fortunately, anesthesiologists have alternative drugs (nondepolarizers) and technics, so that succinylcholine can be avoided where circumstances require.

ACKNOWLEDGMENT

The authors are indebted to George Manners, PhD, head of the Anesthesia Research Laboratory of Dr. Francis Foldes, Montefiore Hospital and Medical Center, Bronx, New York, for the biochemical determinations.

NEW SMOKING MATERIAL The acute effects on airway function from smoking 1 cigarette made with either a tobacco substitute (cellulose base), 30% substitute/70% tobacco or conventional tobacco was determined in healthy nonsmokers and smokers. None of the three cigarettes produced changes in tests of small airway function. Constriction of large airways, as reflected by airway conductance, was produced by the conventional and 30/70 cigarette but not the substitute. The absence of large airway constriction probably results from the lower concentrations of particulate matter in the smoke of the substitute cigarette. Nevertheless, the 30/70 cigarette, which is the proportion likely to be used commercially, was not distinguishable from a tobacco cigarette. *(Costello JF, Douglas NJ, Sudlow MF et al: Acute effects of smoking tobacco and a tobacco substitute on lung function in man. Lancet 2:678-680, 1975)*

Anesthetic Considerations in Patients with Gas Gangrene

MICHAEL J. LAFLIN, LT*
RAYMOND E. TOBEY, CAPT†
J. G. REVES, LCDR‡

Anesthesia for a patient with gas gangrene presents a challenge for the anesthesiologist, since it is an uncommon disease requiring emergency treatment. The authors, faced with such a challenge and finding little guidance in the literature, have proposed modalities of anesthetic management based on pathophysiology, symptomatology, and the reported experience of others. In addition to choice of anesthetic agents, problems reviewed include shock, hypovolemia, tachycardia, fever, anemia, renal dysfunction, pulmonary insufficiency, and contamination. Factors relating to anesthesia during hyperbaric-O_2 therapy are also reviewed.

CLOSTRIDIAL myonecrosis, commonly referred to as gas gangrene, is a serious anaerobic infection. Fortunately, cases occur infrequently, but this may cause unsuspecting physicians to miss the early signs of the disease. Untreated, gas gangrene is uniformly fatal,[1,2] and even prompt and appropriate treatment does not insure survival. Debridement is necessary in most cases and anesthesia is almost always required during this portion of the therapy.

Recently, we were presented with the challenge of administering anesthesia to a severely ill patient with gas gangrene and failed to find any guidance in the literature to help us in our choice and management of anesthesia.[3-7] This prompted us to review the disease process in relation to anesthetic considerations.

DISCUSSION

In order to manage patients with serious physiologic derangements produced by an infecting organism, it is best to be aware of the disease process and, particularly, its alterations of organ systems affected during the course of anesthesia.

Incidence and Mortality.—Although most cases of gas gangrene occur in war casualties, it can follow the trauma of both accidents and surgery. The overall incidence of the disease is unknown. However, in the metropolitan area of Denver, Colorado (population, 1.4 million), for example, there are 3 to 5 cases per year.[8]

Overall mortality with different modalities of treatment ranges from 6.7 to 23%.[4,9] When the infection occurs following surgical procedures, the mortality rate is 33 to 45%, whereas in the case of accidental trauma, it is 10 to 12%.[10,11] This difference has been attributed to the higher index of suspicion in cases of accident compared to hospital-acquired infections.

Types of Infection.—Clostridial infection in man presents a wide spectrum of severity. MacLennan,[6] on the basis of his experience in World War II, has differentiated 3 types of infection on clinical grounds: simple contamination; anaerobic cellulitis; and anae-

robic myositis (clostridial myonecrosis or gas gangrene); of these, only gas gangrene is fatal.

PATHOPHYSIOLOGY

Organisms. — Six *Clostridia* species are capable of producing gas gangrene in man; *C perfringens* (also known as "Welch's bacillus") is the most common causative organism.[1]

Conditions for Infection.—*Clostridia* are found throughout nature and are protected from the lethal effects of ambient O_2 by spore formation. The spores are resistant to most methods of antisepsis but povidone-iodine compresses have been effective in reducing the numbers of skin contaminants.[12] Once *Clostridia* have been introduced into previously healthy tissue, specific alterations in the environment leading to a lowered oxidation-reduction potential must take place before multiplication of organisms can occur. These changes most commonly result from local ischemia.

The incubation period is variable; the average for *C perfringens* is 12 to 24 hours, but incubation periods as short as 1 hour and as long as 6 weeks have been reported.[1,13]

Toxins. — Once conditions suitable for multiplication are met, the increasing numbers of *Clostridia* release powerful exotoxins into adjacent tissues which kill viable cells, turning a benign infection into a potentially fatal disease. At least 12 such exotoxins have been identified from C perfringens[1] of which alpha toxin, a lecithinase, is the primary cytotoxic agent. It diffuses into surrounding healthy tissues where it attacks the lecithin component of cell membranes, causing disruption and lysis of the cells.[1] The *Clostridia* then migrate into these now necrotic areas, release more toxins, and continue their spread in geometric progression.

The other toxins appear to serve as spreading agents for the alpha toxin and as protectors of the infecting organisms from the body's defense mechanisms.

There is no clear understanding of the nature of the systemic toxemia, of the agents that cause it, or of the ultimate cause of death.

Local Effects.—These are the result of the rapidly spreading inflammatory process. The organisms liberate a gas which causes swelling, leading to vascular compression and further spread of the bacteria. The alpha toxin produces destruction and necrosis of muscle and also affects the integrity of capillary endothelial membranes, allowing transudation of fluid and edema formation.

SYSTEMIC EFFECTS

Hematologic. — Intravascular hemolysis and anemia occur with clostridial septicemia, most commonly with postabortal uterine myonecrosis,[1,14] hemolysis apparently resulting from intravascular production of alpha toxin.[1] Subsequent hepatic metabolism of the released hemoglobin leads to hyperbilirubinemia.

Cardiovascular.—The massive edema associated with the local wound, increased insensible loss from fever, and decreased oral intake produce hypovolemia. The common sign of tachycardia is secondary to hypovolemia, hemolytic anemia, fever, and toxemia. Blood pressure early in the course of the disease is normal or slightly elevated, but may fall precipitously to systolic levels of 80 torr or less as the disease progresses.[12] The etiology of the sudden hypotension is unclear.

Renal. — Renal dysfunction and failure occurred in 16% of Roding's patients with gas gangrene; 7.7% of the patients were anuric.[11] The dysfunction most likely occurs as a consequence of hemoglobinemia and hypotension. A circulating nephrotoxin produced by the action of clostridial toxins on uterine muscle has also been postulated.[14]

Thermal.—Temperature changes are variable but generally elevated with an average temperature of 38.3 C (36.1 to 41.7 C) in one series.[10]

TREATMENT

The mainstay of therapy remains debridement, even though other factors have modified the extent of the surgical procedures needed. It is during this phase of therapy that the anesthesiologist becomes involved with the patient and his disease. Since even small areas of involved muscle remaining after debridement may result in death, extensive debridement of all involved areas, including high amputation, has been recommended.[1,9,10]

Adjunctive modes of therapy include massive doses of aqueous penicillin G or tetracycline.[8,9] Some authors suggest that large doses of steroids may be beneficial in cases where the patient is in shock, but there are

no objective data to support this regimen.[8,9,15]

Considerable enthusiasm and controversy have accompanied the use of hyperbaric-O_2 (HBO) therapy. Since the initial encouraging report by Brummelkamp and associates[16] in 1961, many others have used such therapy with success. This therapy does not diminish the mortality rate of the disease but does diminish the degree of debridement required and allows some patients to avoid surgery altogether.[11] Many patients considered inoperable due to extension of the disease onto the trunk have been cured following HBO treatment.[9]

ANESTHETIC MANAGEMENT

Clinical problems of most concern to the anesthesiologist include shock, hypovolemia, tachycardia, fever, anemia, renal dysfunction, pulmonary insufficiency, and the local wound. In addition to these considerations, rapid recovery from the anesthetic is of practical importance, since patients for whom HBO therapy is used must be transported to the chamber for subsequent treatments. The ability of a patient to cooperate during a "dive" would lessen the risk of barotrauma. Another consideration is the requirement for multiple anesthetics during the management of wound closure and skin grafting in patients requiring extensive debridement.

Preanesthetic Assessment.—The most important aspect of the patient's status is the adequacy of his circulating blood volume. Besides noting the usual signs of pulse rate, blood pressure, and central venous pressure, the "tilt test" is a useful, quick, and simple test to help in one's judgment.[17] Fluid input and output changes are so rapid that radioisotope blood volumes are not helpful.

Evaluation of hematocrit is important, since hemolytic anemia may be a preoperative problem. Serum bilirubin, plasma hemoglobin, and CO levels are useful in assessing the patient's hematologic system. The CO level closely reflects changes in hemolytic rates, since it is one of the end-products of hemoglobin metabolism in a stoichiometric ratio.[18,19] Either whole or packed red blood cells should be matched in a volume adequate for replacement of anticipated losses, which in some cases may be large.

Fever is another complicating problem for the anesthesiologist. Antipyretics, cold fluids, and a cooling mattress are indicated in attempting to reduce the elevated temperature. However, operation should not be delayed in an attempt to reduce the temperature.

Monitoring. — Intraoperative monitoring consists of the usual devices employed in poor-risk patients. Esophageal stethoscope, temperature probe, ECG, central venous pressure line, and urinary bladder catheter are essential. In addition, a Swan-Ganz pulmonary-artery catheter and a peripheral artery catheter may be useful in the operative assessment of left heart function and adequacy of ventilation.

Induction.—Patients with gas gangrene often have full stomachs, and anesthesia must be induced with appropriate assurance of a patent airway and precautions against pulmonary aspiration of gastric contents.

Induction agents should be chosen on the basis of the patient's clinical condition. Sodium thiopental should be used with caution in hypovolemic patients, since rapid infusion may lead to hypotension.[20-22] Cardiovascular collapse may occur precipitously in patients with gas gangrene as a component of the disease process, and in these cases ketamine might prove a better choice, particularly when rapid induction of anesthesia is desired. Ketamine has been used successfully in some poor-risk hypovolemic patients;[22] however, its use in gas gangrene has not been studied.

Succinylcholine may be used for rapid muscle paralysis. The anesthesiologist, however, should be aware of the possibility of hyperkalemia and cardiac arrest when succinylcholine is used in the presence of other injuries, such as massive trauma, neurologic injury, or burns, not related to the site of clostridial infection.[23-27] Recent evidence indicates that excessive potassium release may occur as early as 3 to 4 days after injury,[28] which is often within the period of incubation and manifestation of gas gangrene. On the other hand, the large areas of necrotic muscle produced by the infection are relatively isolated from the circulatory system because of the vascular compromise characteristic of the disease, and are unlikely to represent a source of excessive K^+ release.

In cases where rapid muscle paralysis for endotracheal intubation is not necessary, a nondepolarizing muscle relaxant may be used. Pancuronium bromide has been shown to produce adequate relaxation for intubation in 2 to 3 minutes,[29] while supporting the blood pressure and pulse.[30,31] Awake

endotracheal intubation offers an alternative approach.

Maintenance.—The agents of choice for maintenance of anesthesia are not known because of lack of data. We chose halothane because it provides smooth anesthesia with rapid elimination and changes in depth, and can be used with high concentrations of oxygen. Its primary drawback is myocardial depression, but it may also be implicated in the event of jaundice, which occurs in 25% of cases of gas gangrene.[11]

The use of N_2O poses theoretic disadvantages, since it is known to expand air-containing spaces within the body by more rapid diffusion than outflowing nitrogen.[32,33] What effect this property might have on the gas pockets produced by the clostridial infection is speculative. While the "gas" of gas gangrene is primarily H_2, CO_2 is also produced; however, the latter is more soluble and, at least initially, readily absorbed into body fluids.[34]

A natural diffusion barrier to accumulation of N_2O in the tissues is provided by the areas of hypovascular and avascular muscle in which the gas is contained. Since the liberation of toxins has not been inhibited by *in vitro* O_2 exposures of less than 2.5 atmospheres,[35] there is no apparent advantage to the use of high O_2 concentrations. Whether the small pockets of H_2 liberated during debridement represent a fire hazard in the presence of electrocautery is unknown.

Balanced anesthesia or neuroleptanesthesia may be employed, the primary advantage being postoperative analgesia. However, it is important to have a rapid recovery from the anesthetic, since a cooperative patient is easier to manage in the hyperbaric chamber to which the patient may be immediately discharged for postoperative treatment.

Ketamine may be used as the sole agent in conjunction with 100% O_2, but the amount of drug required during a prolonged procedure could delay emergence. Also, an increase in the already elevated heart rate might increase myocardial O_2 demand in a heart with reduced reserves.

Nondepolarizing muscle relaxants are useful and should be selected according to clinical needs. Pancuronium and gallamine are indicated in hypovolemic patients but may increase an already elevated heart rate. Because of the potential development of renal failure, gallamine should be used judiciously. Curare should also be used cautiously because of its potential for producing hypotension. A need for postoperative ventilatory support with inadequate reversal of relaxants could be a serious problem, if the patient is to be transported to a hyperbaric chamber with limited access to the patient and little space available for a ventilator.

Spinal and epidural anesthesia are not recommended because of the unstable cardiovascular status. The possibility of introducing infection should also be considered. A brachial plexus block may be acceptable in the case of disease limited to the upper extremity, but one must bear in mind that a hematoma following the axillary approach could compromise vascular supply to tissue which already has only a marginal perfusion and O_2 supply. It may also be difficult to assess the proximal spread of the infection in deep muscle planes, and the tissues of the axilla may be involved.

As in all major surgical procedures, adequate crystalloid, colloid, and blood-component therapy is imperative. Such clinical signs as pulmonary capillary wedge pressure, central venous pressure, and urine output are useful in judging the adequacy of volume replacement.

CONTAMINATION

The final concern in anesthetic management is the problem of a patient with an infected wound. *C perfringens* species rarely form spores during active infection and, being obligate anaerobes, any vegetive organisms exposed to air should be rapidly neutralized.[36] The *Clostridia* species causing gas gangrene are only opportunistic pathogens,[37] and are not highly invasive except under conditions leading to a lowered oxidation-reduction potential.[36] Since the conditions suitable for infection occur only rarely,[37] cross-infection is unlikely.

MacLennan[6] found that only 1.5% of war wounds contaminated with *Clostridia* developed gas gangrene. When 2 cases of gas gangrene occurred within a 2-day period in 1 hospital, an epidemiologic study showed no relation between the 2 causative organisms.[12] The study further confirmed the widespread distribution of *Clostridia* spores. They are frequently found as a result of fecal contamination, but are also found in soil, dust,[34] clothing,[1] and even in low numbers in operating rooms.[12]

Thus, the rarity of spore formation, the ubiquitous nature of the organism, and the stringent conditions required for infection make isolation of patients unnecessary. The most effective means of sterilization of anesthesia equipment is steam autoclaving, but this, also, is probably unnecessary and in many instances impractical.

Guest Discussion

G. DOUGLAS BLENKARN, MD
Department of Anesthesia
Duke University Medical Center
Durham, North Carolina

Dr. Laflin's study presents the common combination in clinical gas gangrene: the ubiquitous presence of the seed (the clostridial spore) and the appropriate culture media (hypoxic tissue). The prerequisites of proper anesthetic management of these patients are identical to those of any critically-ill septic patient and include confirmation homeostasis of gas exchange by intermittent arterial blood-gas analysis and continuous direct monitoring of ECG, arterial and central venous pressure, and urine output.

Anesthetic agents selected are of less importance than the manner in which they are employed. We feel that anesthesia should be sufficiently light so as not to compromise cardiovascular reactivity. Accordingly, we would almost always select a narcotic-muscle relaxant technic, with supplementation by a volatile inhalation agent only if oxygenation was impaired.

It is now widely felt that the initial 3 hyperbaric-O_2 (HBO) treatments during the initial 24 hours are the most crucial. Whether surgical debridement or HBO is employed first after the presumptive diagnosis is reached depends upon the logistics of the situation. Ideally, all therapeutic modalities should be employed in every case of gas gangrene. If appropriate hyperbaric facilities and expertise are close at hand, and if the same standard of intensive care can be provided within the chamber, then no impediment exists to using this important adjuvant therapeutic modality.

Decompression sickness is never a problem for the patient, as he breathes close to 100% O_2. Difficulty in equilibrating the middle ear with the chamber pressure (barotrauma) is readily prevented by prophylactic myringotomy immediately upon recognition of any problem during the initial hyperoxic exposure.

During HBO treatment, it is essential to ensure delivery of close to 100% O_2 as the inspired gas and to confirm the expected degree of hyperoxemia by arterial blood-gas analysis performed within the chamber. As a significant physiologic shunt is present in almost all these patients, the theoretic high O_2 tensions (in excess of 1800 torr) are rarely achieved. A Pao_2 of greater than 1000, however, is acceptable while breathing 3 atmospheres of O_2 and hyperoxygenates perfusing tissues at the advancing edge of the infection, helping to arrest the vicious cycle of tissue death described by Dr. Laflin.

Central nervous system hyperoxic toxicity, as manifested by a general convulsion, is not uncommon. It can be minimized by appropriate sedation, treating hyperpyrexia, planned midway interruption of each HBO treatment with 5 minutes of air breathing, and by being alert to the appearance of any preconvulsive symptoms or signs, such as abnormal acuteness of hearing, nausea, or focal twitching.

However, if the logistics are such that HBO therapy significantly compromises any of the other modalities of therapy, one should forego HBO treatment.

Two other aspects of oxygenation deserve emphasis. Large amounts of blood are frequently required to replace that lost due to hemolysis and during and following surgical procedures. Also, the adequacy of oxygenation must be assured in the intervals between HBO exposures. Indeed, every patient should receive supplemental O_2 continuously until the infection is well under control and arterial oxygenation is adequate while breathing air.

Unfortunately, the general reaction of hospital personnel to patients with gas gangrene is analogous to their reaction to patients with venereal disease, so that gas-gangrene patients are not only isolated from other surgical patients but are frequently excluded from first-class intensive care by being sequestered in small isolation rooms.

Theoretic Significance of pH Dependence of Narcotics and Narcotic Antagonists in Clinical Anesthesia

DONALD W. BENSON, MD, PhD*
JOYCE J. KAUFMAN, PhD†
WALTER S. KOSKI, PhD‡
Baltimore, Maryland§

Determination of the effect of pH and temperature on pK_a partition, and drug distribution coefficients in a series of common narcotics and their antagonists has shown that within the range of blood pH (7.1 to 7.7) encountered in the practice of anesthesiology, marked differences of distribution of the drugs between a model lipid (octanol) and water can occur. When these data are considered in the light of clinical experience with narcotics used in patients undergoing or recovering from surgical procedures, a correlation between the depth and duration of narcosis or the efficacy of narcotic antidotes and ventilatory status is seen. This correlation can be explained in part if the influence of blood pH on the probable CNS/blood distribution of a given drug is taken into consideration. Support is given to this proposal by representative studies in the literature. The very different drug distribution coefficients of two closely related narcotic antagonists, naloxone and naltrexone, correctly predicted the faster onset and shorter duration of the former, which was confirmed by reported clinical observations.

WE RECENTLY measured, by microelectrometric titration,[1,2] pK_a‖ and partition coefficients, and drug distribution coefficients between octanol and water as a function of pH and temperature[3-6] in a number of clinically used narcotics and narcotic antagonists. The partition coefficients and drug distribution values at 37° C are higher than those at 20° C,[6] the temperature at which such measurements have usually been made. There are significant nonuniform increases in the drug distribution coefficients between 20° and 37° C, ranging from 21% for morphine to 200% for naltrexone.

The nonregularity of increase with temperature emphasizes the necessity for measurements at 37° C, since our study[6] showed that extrapolation of measurements made at lower temperatures to body temperature by any constant factor is not valid. Partition coefficients (P) refer to the partitioning of the same species, in this case the free base, between oil and water. Drug distribution coefficients $P_{apparent}$ (P_a) (or apparent partition coefficients), refer to the distribution

‖pK_a: The negative logarithm of an apparent ionization constant, K′. The buffering power of a buffer system is highest when pK′ = pH.

$$P_a = \frac{[\text{free base} + \text{acid salt}]_{\text{lipid}}}{[\text{free base} + \text{acid salt}]_{\text{water}}} \simeq \frac{[\text{free base}]_{\text{lipid}}}{[\text{free base} + \text{acid salt}]_{\text{water}}}$$

(since essentially it is only the free base which partitions into the lipid).

These drug distribution coefficients are related to the amount of drug that will pass the blood-brain barrier and enter the CNS, and are the pharmacologically significant quantities when considering drug dosages. Reporting our data as P or P_a rather than as the more customary, less sensitive, log P, enables clinically significant differences to be ascertained. The narcotics investigated included morphine, codeine, oxymorphone, levorphanol, meperidine (pethidine), methadone, and alpha acetylmethadol (a derivative of methadone with a longer duration of narcotic action, being tested clinically in experimental drug addiction). (It should be noted that the narcotic properties of codeine occur as a result of its demethylation.) The narcotic antagonists investigated included nalorphine (a mixed agonist-antagonist), naloxone, naltrexone (the N-cyclopropylmethyl derivative of oxymorphone), levallorphan, cyclazocine, and pentazocine (the two latter are classed as mixed agonist-antagonists).

METHODS

The microelectrometric titration apparatus used in this study is an adaptation of conventional assemblies. It consisted of a small thermostatted cell in which about 0.04 mM of sample was dissolved in 5 ml of CO_2-free triple-distilled water. A blanket of N_2 gas was maintained over the sample to prevent any absorption of CO_2 from the room atmosphere. pH measurements were made with a PHM64 radiometer pH meter with calomel-and-glass electrodes. A microburet coupled with a microdelivery tip permitted accurate additions of small quantities of titrant (2N NaOH). A magnetic stirrer was used for proper agitation.

In determining the pK_a, a conventional titration curve in which one plots volume of titrant versus pH is obtained. A blank titration curve prepared in the same manner, but without the sample, was subtracted from the first curve. This resultant curve has a shape represented by the following equation

$$pH = pK_a + \log\frac{\alpha}{1-\alpha}$$

The pH at which α, the fraction of sample in the dissociated state for acids or the associated state for bases was 0.5, was taken as the pK_a.

The distribution coefficient of the drug was determined by titrating the compound in a two-phase system (octanol and water). If a compound is added to such a two-phase system in an amount insufficient to saturate either of the phases, the material will distribute between the two phases in a definite proportion determined by its distribution coefficient (P). Octanol is used to simulate the lipid because of its wide use as standard in such applications.[7]

The compound dissociates into its respective ions in the aqueous phase. The extent of the dissociation is determined by the dissociation constant (K_a), which was obtained from the experimentally determined titration curve. When the drug is titrated in the presence of a finely dispersed oil, the free acid or base rapidly partitions between oil and water and, as the titration proceeds, the dissociation equilibrium in the aqueous phase continues to follow the relation

$$K_a' = \frac{[H^+]\,[A^-]}{[HA]}$$

for the acid (HA), and a corresponding relation applies when a base is used. The removal of HA into the oil results in a shift in the apparent pK_a by an amount which depends on the volumes of water and oil present (the shift occurs to higher pH if an acid is titrated and to lower pH if a base is titrated in the presence of the two-phase system). This shift can be simply related to the distribution coefficient (P) by the equation

$$P = \frac{V_w\ (\text{antilog}\ pK_a' - 1)}{V_o}$$

in which the volumes of water (V_w) and oil (V_o) are known. From the measured shift of pK_a' ($\triangle pK_a'$), the distribution coefficient can be calculated.

RESULTS AND DISCUSSION

The marked sensitivity of the drug distribution coefficients to pH in the range from 7.1 to 7.7 may have significant consequences in a variety of clinical situations. These data at 37° C, encompassing the physiologically significant pH range 7.1 to 7.7, are presented in the table.

We have observed* that surgical patients under narcotic analgesia (for example with meperidine) and concomitant N_2O-O_2 anesthesia, if hyperventilated during the course of the operation, exhibit a deeper plane of analgesia, almost as if they had been given larger doses of narcotic. The data in the

TABLE

Drug Distribution Coefficients at 37° C as a Function of pH

	pK_a	P7.1	P7.35	P7.4	P7.45	P7.5	P7.6	P7.7
Morphine sulfate	7.93	0.80	1.30	1.42	1.54	1.68	1.98	2.30
Codeine phosphate	8.10	1.25	2.07	2.28	2.51	2.75	3.30	3.91
Nalorphine HCl	7.59	17.55	26.22	28.16	30.16	32.19	36.39	40.41
Oxymorphone HCl	8.17	0.53	0.89	0.98	1.08	1.19	1.43	1.71
Naloxone HCl	7.82	19.49	30.82	33.55	36.42	39.43	45.79	52.54
Naltrexone HCl	8.13	7.11	11.86	13.08	14.40	15.82	18.99	22.57
Meperidine HCl	8.50	20.20	34.87	38.82	43.17	47.96	58.99	72.17
Methadone HCl	9.26*	58.68	103.81	116.33	130.30	145.92	182.92	229.04
α-acetylmethadol HCl	8.61*	611.81	1063.02	1185.25	1321.03	1470.46	1817.45	2235.98
Levorphanol tartrate	9.36*	6.89	12.21	13.69	15.34	17.18	21.56	27.02
Levallorphan tartrate	8.50*	116.63	201.35	224.17	249.30	276.95	340.66	416.76
Cyclazocine	9.38*	10.86	19.21	21.54	24.14	27.05	33.94	42.55
Pentazocine	9.16*	55.99	98.89	110.76	124.00	138.81	173.79	217.29

*$pK_{a(H_2O)} = pK_{a(50\%\ EtOH - H_2O)} + 0.5$ pH.

The tabulated partition coefficients represent averages of at least 4 determinations in the range of 2 to 20% oil in water. As expected, precision was poorest in cases where pK_a shift was smallest. In such cases as morphine sulfate or oxymorphone HCl, maximum scatter was about 15% of the value listed. In other cases it was much smaller.

table show that the drug distribution coefficient of morphine is raised 62% when the pH of the aqueous phase is changed from 7.4 to 7.7. This rise in drug distribution coefficient will be exhibited to a greater or lesser extent by all narcotics having a protonated amine.

Thus, it seems appropriate for the anesthesiologist giving narcotics preoperatively or during an operation to consider the effect of hyperventilation during anesthesia. The almost threefold increase in the drug distribution coefficient of morphine between pH 7.1 and 7.7 indicates that possible respiratory and/or metabolic alkalosis or acidosis may have a considerable effect on the degree of narcosis achieved.

Use of naloxone to back-titrate patients given morphine was described recently.[8] Since naloxone also exhibits a marked 57% rise in drug distribution coefficient from pH 7.4 to 7.7 (and a marked 42% decrease from pH 7.4 to 7.1), it would appear that dosage might be pH-dependent as well as time-and-quantity dependent.

Another area where pH-dependent distribution of narcotics may be important is in obstetrics. The blood of an infant during parturition and shortly after birth is more acidic (~7.2) than that of the mother.[9] Thus, it would be expected that the blood levels of basic drugs would be higher in the infant than in the mother if placental transport occurred by rapid passive diffusion of the unionized drug.[10] The placental barrier is mainly lipoprotein in nature; therefore, lipophilic drugs can pass more easily. Once the free base (unionized) form of the drug has traversed the placental barrier from the mother to the fetus (which is governed by the lipid-water drug distribution coefficient), the lower the pK_a of the narcotic (or narcotic antagonist), the more it is apt to become concentrated in the fetus, since only the free base can retraverse the placental barrier.

In the study of Beckett's group,[10] cited above, pentazocine and meperidine were given both singly and in combination to parturients in labor. Pentazocine was found to have a lower concentration in the newborn than in the mother, whereas the concentrations of meperidine in the newborn were higher than those in the mother. Those authors suggested that meperidine traversed the placental barrier more rapidly than pentazocine.

Our data would suggest an alternative explanation. The drug distribution coefficients of pentazocine are considerably higher at all pH values than those for meperidine. The lower pH of the fetal blood compared to that of the mother resembles a two-compartment system. Some of the unchanged free base of both narcotics will be converted into the acidic form and thus be unable to traverse the barrier in the reverse direction. The pK_a of meperidine at 37° C (8.5 by direct titration in H_2O solution) is lower than that of pentazocine (9.16 extrapolated to 100% H_2O from titration in 50% EtOH-H_2O solution). Thus, the lower pH of the fetus would cause proportionately more meperidine than pentazocine to convert back to the protonated form, and as a result relatively more of the pentazocine than of the meperidine entering the fetus would be able to retraverse the placental barrier back to the mother.

The reversal effect of nalorphine or naloxone and their pH dependencies may also be especially important in obstetrics. Where heavy medication with narcotics is used during labor and a narcotic antagonist is given the infant, there is significant acidosis in depressed babies.[11-13] Our drug distribution data would suggest that nalorphine would be 20 to 25% less effective at pH values of 7.15 to 7.23, as noted in the cited studies, than at normal pH value of 7.4. Our data suggest that naloxone would probably pass into the CNS only marginally more effectively than nalorphine at these low pH values. However, the data further indicate that hyperventilation to a higher pH would make nalorphine a more effective antagonist, since the drug distribution coefficient is higher at higher pH values. For the same reason, hyperventilation would also increase the antagonist efficiency of the naloxone.

The drug distribution coefficient of naltrexone is significantly lower than that of naloxone, more than might have been expected from the similarity in their structures, with naltrexone being significantly less lipophilic than naloxone. We had postulated that this would lead naloxone to have a more rapid onset for antagonist activity and likewise a shorter duration of action than naltrexone.[4] Clinical studies confirmed this prediction.* The lower oil/water drug distribution coefficient of naltrexone might indicate a larger dosage of naltrexone than of naloxone to be necessary for effective antagonist activity.

Management of Intractable Pain in Adiposis Dolorosa with Intravenous Administration of Lidocaine

TADASHI IWANE, MD*
MASANORI MARUYAMA, MD†
MICHIKO MATSUKI, MD‡
YUSUKE ITO, MD§
KOKI SHIMOJI, MD‖
Niigata, Japan**

Intractable pain in a patient with adiposis dolorosa (Dercum's disease) was treated by IV administration of lidocaine (200 to 400 mg). Relief was maximum 20 minutes after the end of drug infusion and persisted for over 10 hours. Toxicity was minimal. Slow EEG waves which appeared during drug administration disappeared within 20 minutes.

DERCUM[1] described 3 cases of adiposis dolorosa (Dercum's disease) as long ago as 1892, but the etiology of this condition is still unknown. Common characteristics of Dercum's disease have been described as follows:[2]

1. Painful diffuse fatty deposits except in the face, the backs of hands, and the insteps.

2. Postmenopausal women are most often affected.

3. Asthenia, weakness, and fatigue are marked.

4. Psychic phenomena, including neuroses and emotional instability, are common.

No successful treatment of the disease has yet been established, but partial relief of pain by IV administration of lidocaine appears of palliative value.

CASE REPORT

A 48-year-old woman was admitted to the Niigata University Hospital on October 14, 1974, with the chief complaint of intractable pain over the whole body which was exacerbated by touch or pressure.

In 1968 she was treated with dexamethasone for pain in the right hip joint. In October 1969, she underwent an operation on her right hip joint, following which edema of the lower extremities was treated with diuretics.

In May 1972, pain in all joints as well as butterfly-like erythema on the face appeared; this was diagnosed as systemic lupus erythematosus (SLE). At that time, fatty deposits appeared in the left forearm and her

body weight increased, with pain due to pressure over her whole body.

In June 1973, she was examined at a university hospital and SLE was suspected. In February 1974, she experienced unconsciousness for about 30 minutes. Subsequently, her movements were accompanied by increased spontaneous pain, hyperalgesia, and thermohyperesthesia. Psychiatric and EEG examinations revealed that, although hysteria could not be ruled out, Dercum's disease was probable.

On November 20, 1974, the patient presented in a wheel chair. She was obese, weighing 66 kg at a height of 150 cm, with fat deposits general except on her face, hands, and insteps. Her entire body surface was painful to the touch. She complained that her right shoulder and hip joint were so painful that walking was difficult. She could bathe only in tepid water because of thermohyperesthesia, and complained of insomnia.

Lidocaine (200 mg) was administered IV over 35 minutes. Ten minutes after the start of administration, the patient developed a feeling of heat, flushing of the breasts, euphoria,[3] numbness, and appeared hypnotized. Blood-gases analyzed immediately after drug administration were within normal limits. The patient complained of a slight headache 10 minutes after the end of administration.

She is presently (April 1975) being treated on alternate days with 400 mg of IV lidocaine given over a 15-minute period. Maximum relief is observed about 20 minutes after drug administration and relief continues for over 10 hours. Pain relief in the distal region of the bilateral elbow joints is now marked, mobility of the thumbs and fingers is improved, and she walks more easily than previously. However, some pain in the right shoulder and hip joint has persisted.

DISCUSSION

Despite several reports on Dercum's disease, optimum analgesia has not yet been described. Tetraethylammonium chloride[4] and epidural or spinal anesthesia[5] have been tried but with only partial success. As Dercum found connective tissue infiltration around the nerves in fatty deposits, neuritis has been suspected as the cause of pain,[5] but this theory has not been confirmed.

Local IV anesthetics have been used for management of pain due to burns, cutaneous cicatrices, dermatomyositis, pruritus, and cardiac arrhythmias.[6,7] However, the mechanism of action of these agents has not been elucidated. Lidocaine may block impulse conduction in peripheral nerves[8] and depress cerebral activity,[9] which may result in increased pain threshold. Central effects of some local anesthetics have been reported to be biphasic,[9,10] a small dose having an anticonvulsive activity while a large dose may induce convulsions. Sakabe's group[9] found that small doses of lidocaine (3 to 15 mg/kg) depressed the cerebral metabolism dose-dependently, reflected by a decrease in cerebral metabolic rate of O_2 consumption and an inhibition of electrical activity of the brain.

In our patient, the EEG showed slow waves, which appeared in 7 minutes after the start of administration and disappeared within 20 minutes after the end of drug administration (fig 1). By contrast, the pain relieving effect was found to be maximum at about 20 minutes after the end of administration. This suggests that pain relief following the administration of lidocaine may not depend on depression of cerebral activity but on its effect on peripheral nerves. The ECG, blood pressure, pulse rate, and respiratory rate have shown no remarkable changes during or after lidocaine administration (fig 2).

Arthralgia, however, has been only slightly alleviated even by this treatment and ankylosis has kept the patient almost bedfast. Thus, while lidocaine administration has not effected a complete cure, it has at least provided substantial relief for the otherwise intolerable pain of Dercum's disease.

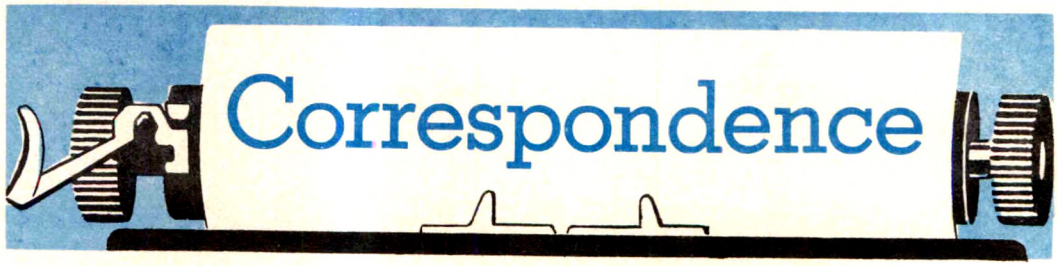
PRACTOLOL The selective effects of low (1.5 mg/kg) and high (12 mg/kg) doses of oral practolol on beta-1 and beta-2 receptors was evaluated in 10 volunteers. Low doses of practolol produced 40 per cent blockade of the heart rate response to exercise but did not alter forearm vasodilator responses to isoproterenol. In contrast, the high doses produced blockade of both cardiac and vascular responses. The beta-1 blockade was not greatly different between the 2 doses. Thus, a low practolol dose blocks beta-1 responses but at higher doses this selectivity is lost as beta-2 responses are also blocked without any additional blockade of chronotropic responses. *(Lertora JLL, Mark AL, Johannsen UT et al: Selective beta-1 receptor blockade with oral practolol in man. A dose related phenomenon. J. Clin Invest 56:719-724, 1975)*



To the Editor:

I was interested to read the report by Orr,[1] describing the reversal by physostigmine of delirium induced by ingestion of the flowers of the plant *Datura stramonium*.

A member of this family of plants, *Datura arborea* (popularly known as "trumpet lily"), is widely distributed in this state, and earlier this year one of a group of 7 youths died after ingesting its flowers, the others developing a delirium lasting some 18 to 24 hours.

Based on the similarity between the symptoms of *Datura* poisoning and the central anticholinergic syndrome,[2] I suggested elsewhere at the time[3] that the centrally-active anticholinesterase, tetrahydroaminacrin (tacrine, THA) [Romotal®] would effectively reverse the symptoms and signs of such poisoning, as unfortunately physostigmine for parenteral use is not available in Victoria.

Orr's comment that further encounters with *Datura* can be anticipated appears relevant to both countries, and the availability of a specific antidote should be widely publicized.

Editor's comment: Unfortunately, no form of tetrahydroaminacrin is commercially available in the USA, although Romotal® can be found in most European countries.

Editors share the belief that medical writing is capable of vast improvement. This article is one of a series of personal communications from Charles G. Roland, M.D., former Senior Editor of JAMA, to John T. Martin, M.D., Associate Editor of Anesthesia & Analgesia . . . Current Researches. Dr. Roland is Chairman, Department of Biomedical Communications, Mayo Clinic, Rochester, Minnesota 55901.

Thoughts About Medical Writing

XXXIV. The Publication Process

Dear Tom:

The world of medical publication is a mystery to all but a few insiders. Of the whole population of physicians, relatively few write for publication. And of those who do, only a small fraction write often enough to become acquainted with the details of the process or to have a reason to be concerned with matters such as priority or publication ethics.

Part of the difficulty is that we know little about publication, in the scientific sense of knowing; the process itself has been little studied. The critical evaluation of the whole field, which can be termed the sociology of medical knowledge, is only beginning to be carried out.

Some examples are outstanding exceptions to this generality. For instance, Merton has studied multiple discoveries of the same fact or observation.[1] He has noted that it is not at all unusual for two or more investigators to make the same observation independently. This is a common phenomenon. Not only that, Merton has pointed out that disputes about priority are common and natural; he has found it almost a rule that a scientist who writes his biography and who claims to have no major concern for priority will, within a few pages, make such a claim. Or, as Merton put the thought in more general terms: "The expression of disinterested moral indignation is a signpost announcing the violation of a social norm."[2]

So it seems that it is normal to expect other investigators to be studying the phenomena that interest you. And it is just as normal for someone who has achieved priority to want public credit for it—and to seek out the credit, if necessary.

There are other "normalities" that fit into this study called the sociology of medical knowledge. Price, in one of the best known investigations in the field, brought to prominence the principle of doubling times for scientific knowledge. The number of scientific journals, for example, has doubled about every 15 years since journals first were published three centuries ago. An even more impressive extrapolation is Price's statement that "we can say that 80 to 90 percent of all the scientists that have ever lived are alive now."[3]

We are, then, beginning to know some facts about scientific knowledge itself. But, as in all fields of science, every casual assumption needs quantification and verification. In my opening paragraph I said that relatively few physicians write for publication. How few? Of those who write, is it true (as has been shown in other fields)

that only 10% of the writers write 90% of what is written? And if so, what does it mean? Someone needs to study those questions.

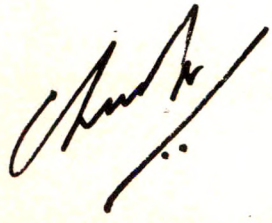
On a much smaller scale, we need to know more about the actual publication process itself. One recent study was devoted to 103 papers published from the Mayo Clinic. When these papers were categorized by type, it was found that both laboratory research papers and clinical research papers had an average span of over 4 years. That is, from the time the chief investigator had his or her idea to do a certain study, until the publication of the results of the study, took that long. For case reports it was more than 2 years and for review articles it was more than 3 years.[4]

This same study showed that journal handling times were not remarkably long, even though the impatient author may find this difficult to believe. The time lapse from submission of an article to its ultimate publication (85% of the papers being accepted by the journals to which they were first submitted) ranged from 25% to 30% of the total span.

Other data come from such investigations —some of it seemingly trivial. More than 80% of the authors write out their manuscripts longhand[4] (and so do I). One percent of these authors never revise their manuscripts; the first draft is good enough for them.

What does all this lead to? We know a little about the sociology of the way we acquire and distribute knowledge. We need to know much more. Simplistically, perhaps, we may come to believe that knowing more about the medical *writing* aspects of the process could help ease the task of the writer in some way; one fact is certain—most medical writers don't enjoy the writing itself. Yet I must admit a bias. I don't think that writing is supposed to be easy. Wasn't it Sheridan who said "Easy writing's curst hard reading"?

Regards,



[Charles G. Roland, M.D.]

SILICONE CATHETERS Silicone elastomer intravenous catheters were used to provide total intravenous nutrition for an average 20.4 days (range 4 to 56 days). A crank introducer unit permitted the catheters to be introduced into the basilic or cephalic vein and then advanced into the superior vena cava. Thirty of 36 catheters were removed because they were no longer needed. Thrombophelbitis developed in 2 patients when the catheter tip was in the axillary vein and in 2 patients when the catheter had been inserted into previously punctured veins. Advantages of the silicone catheters are flexibility reducing the chances for vessel perforation or intima damage, minimal thrombogenicity, tissue compatibility and radiopacity. This approach offers an alternative to placing the catheter in the neck. *(Hoshal VL: Total intravenous nutrition with peripherally inserted silicone elastomer central venous catheters. Arch Surg 110:644-646, 1975)*

A Comparative Study of Enflurane and Halothane Using Systolic Time Intervals

JOEL A. KAPLAN, MD*
EDWARD D. MILLER, MAJ, MC†
DANIEL R. BAILEY, MAJ, MC‡

The effects of enflurane and halothane anesthesia on systolic time intervals were studied in 12 healthy patients. Cardiovascular measurements were made at equipotent levels of anesthesia: enflurane 1.23% end-tidal and halothane 0.65% end-tidal. These agents were studied first with 50% N_2O and then without N_2O. Systolic, diastolic, and mean arterial blood pressure were decreased more by enflurane than by halothane ($p<0.05$). However, halothane caused significantly more myocardial depression than enflurane, as indicated by a larger preejection period (PEP) and preejection period/left ventricular ejection time (PEP/LVET) and a smaller $1/PEP^2$ and ejection fraction. When N_2O was discontinued, both agents increased PEP and PEP/LVET and decreased $1/PEP^2$ and the ejection fraction.

WHEN administered in clinical doses, enflurane produces a stable cardiovascular system. Spontaneous arrhythmias are unusual except for an occasional nodal rhythm. Marshall and associates[1] showed, in 6 healthy patients, that during enflurane anesthesia (1 MAC), the cardiac index is only minimally reduced at normocarbia and hypocarbia, and is elevated at hypercarbia. Previously, Prys-Roberts and colleagues[2] had shown, in patients anesthetized with similar concentrations of halothane, that there is a marked reduction in cardiac index at all levels of CO_2. Bahlman's group[3] demonstrated that cardiac output decreased after 1 hour of halothane anesthesia but increased to levels above control at the end of 5 hours of anesthesia.

It is still unclear whether enflurane differs from halothane as a negative inotropic agent. *In-vitro* studies using cat papillary muscle have produced conflicting results. Studies by Shimosato and colleagues[4,5] on contractile parameters have shown halothane to be more of a depressant than enflurane, but a study by Brown and Crout[6] showed enflurane to be the most depressant of 5 general anesthetic agents. These *in-vitro* studies raise questions of differences in species, experimental design, and *in-vitro* versus *in-vivo* situations.

The measurement of systolic time intervals is a noninvasive technic that has been shown to correlate well with direct internal measurements of left ventricular function (LVF) in man.[7] Martin and coworkers,[7] studying 6 patients during cardiac catheterization, found identical values whether systolic time intervals were measured externally or internally. Following acute pharmacologic intervention, the preejection period (PEP) and left ventricular dp/dt correlated well and varied inversely.

Paper received: 5/13/75
Accepted for publication: 9/8/75

As there have been no comparative studies of the cardiovascular effects of enflurane and halothane in man, the purpose of the present study was to use systolic time intervals to compare these anesthetic agents, in normal man, in a totally noninvasive manner.

METHODS AND MATERIALS

Two groups, each comprising 6 healthy young patients (all ASA class I), and equally divided between men and women, were studied in a quiet room prior to elective minor surgery. Their mean age was 28 years (range 19 to 39). All had given informed consent and were studied at 0700 hours after an overnight fast. Dextrose in lactated Ringer's solution (1000 ml) was administered IV ½ hour before the study. No premedication was given and no patient was taking any medications.

Awake control measurements of systolic time intervals, blood pressure, and heart rate were recorded. Patients were then preoxygenated for 5 minutes. At that time, 100% N_2O was administered for 60 seconds for a rapid anesthesia induction in order to avoid an excitement stage, and patients were maintained on 50% N_2O-O_2 with either 1% inspired halothane or 2% inspired enflurane by mask. A semiclosed-circle absorber system was used with total gas flow rates of 10 L/min for 5 minutes and then 5 L/min. Spontaneous respirations were maintained throughout the study.

After 30 minutes of stable anesthesia, the following measurements were made: (1) systolic time intervals, (2) blood pressure and heart rate, (3) end-tidal CO_2, and either end-tidal enflurane or halothane (end-tidal gas samples were taken via a 16-gauge catheter placed at the distal tip of a long oral airway), and (4) arterial blood gases. Then the N_2O was discontinued and all measurements were repeated 20 minutes later.

The systolic time intervals were measured by the following standard technic (fig 1): A simultaneous fast-speed recording at 100 mm/sec of a phonocardiogram, carotid arterial pulse wave, and ECG were made on an Electronics for Medicine (EM) monitor. The phonocardiogram was recorded with an EM PS-2 heart-sound microphone placed over the upper precordium to give the best recording of the 2nd heart sound. The carotid arterial pulse wave was recorded with a Statham P23Db pressure transducer attached to a funnel-shaped receiver. The ECG lead with the clearest onset to the QRS complex was chosen.

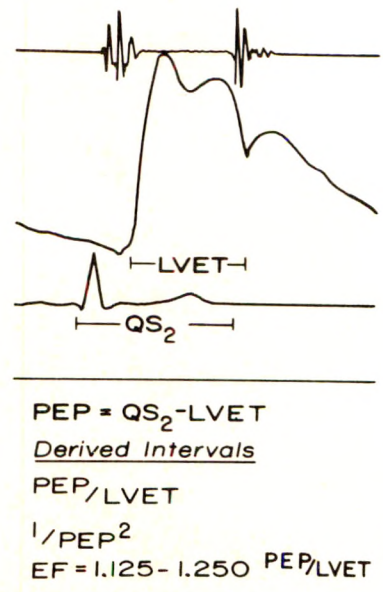

FIG 1. Systolic time intervals measured by the phonocardiogram, carotid arterial pulse trace, and the ECG. Upper part of figure shows how QS_2 and LVET are measured; lower part shows derived parameters.

Three time intervals were measured: (1) total electromechanical systole (QS_2), measured from the Q-wave of the ECG to the first major deflection of the 2nd heart sound; (2) left ventricular ejection time (LVET), measured from the initiation of the carotid upstroke to the dicrotic notch; (3) PEP, calculated by subtracting the LVET from the QS_2. From these measurements, PEP/LVET, $1/PEP^2$, and the ejection fraction were derived. The formula for ejection fraction ($EF = 1.125 - 1.250$ PEP/LVET) was shown by Garrard and associates[8] to have a close correlation ($r = 0.9$) with the ejection fraction measured at cardiac catheterization. All measurements were corrected for heart rate, using Weissler's regression formulas, except for PEP/LVET, which is independent of heart-rate changes between 40 and 110 bpm.[9] All systolic time-interval measurements were made by hand. All values presented are the means of 10 consecutive intervals, which usually included two respiratory cycles.

Statistical comparisons were made using paired *t*-tests within anesthetic groups and unpaired *t*-tests between anesthetic groups.

‡$p<0.05$ compared with control.

RESULTS

When given for 45 minutes, both enflurane and halothane resulted in end-tidal concentrations of 0.8 MAC (table 1). The arterial blood gases shown in table 1 indicate a Pao_2 greater than 150 torr at all times during the study. The $Paco_2$ was higher in the enflurane group, but this difference was not statistically significant, due to large patient variability.

Both agents showed a significant decrease in systolic, diastolic, and mean arterial blood pressure (MAP) from their control values (table 2). However, the MAP decreased more in the enflurane group (22%) than in the halothane group (9%). Heart rate did not change significantly in either group. No arrhythmias were seen with either agent.

Of the 3 time intervals measured, PEP is the best indicator of overall myocardial performance. A decrease in myocardial contractility causes a prolongation of PEP and a shortening of LVET. Both agents (fig 2) caused a significant prolongation of PEP ($p<0.05$); however, halothane prolonged PEP significantly more than enflurane

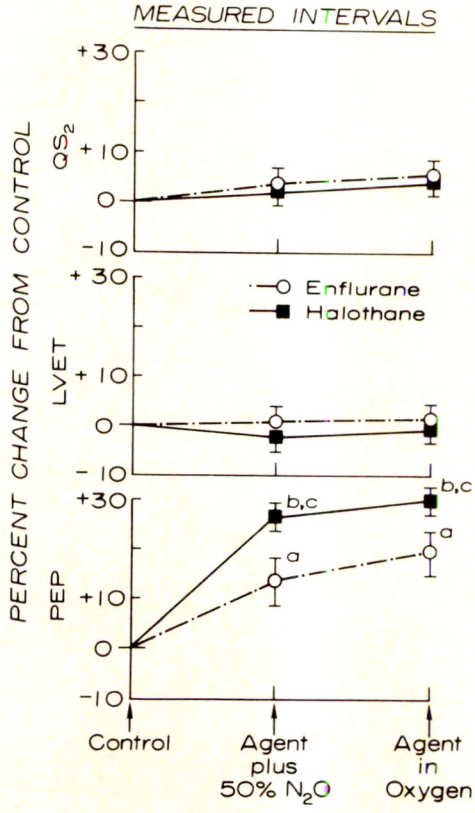

FIG 2. The three measured systolic time intervals shown as percent change from control values. All points represent mean values ± 1 SE of 6 subjects. a = $p < 0.05$ compared with control; b = $p < 0.01$ compared with control; c = $p < 0.05$ compared with enflurane.

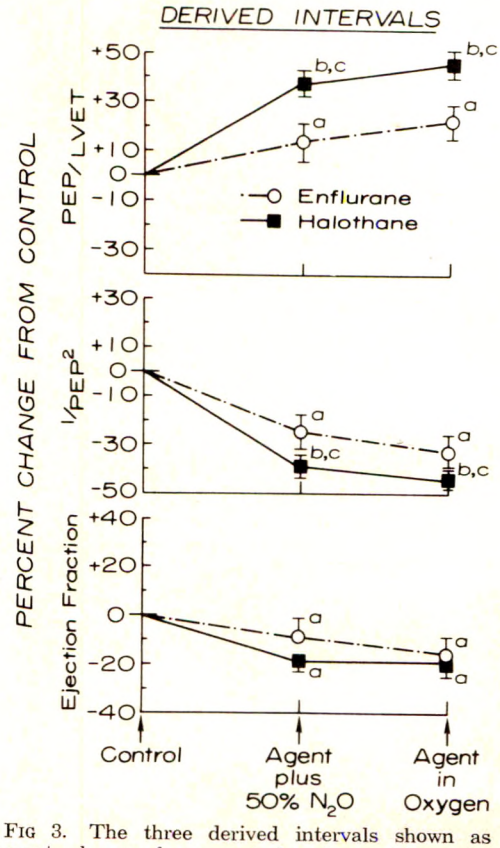

FIG 3. The three derived intervals shown as percent change from control values. All points represent mean values ± 1 SE of 6 subjects. a = $p < 0.05$ compared with control; b = $p < 0.01$ compared with control; c = $p < 0.05$ compared with enflurane.

($p<0.05$). Also, halothane shortened LVET slightly more than enflurane.

In previous studies, measured intervals by themselves have not correlated as well with invasive measurement as have some derived parameters.[7] Thus, figure 3 shows the percent change from control of the three derived intervals. The control values were all within normal limits. Both anesthetic agents caused a significant increase in the PEP/LVET ratio and a significant decrease in $1/PEP^2$ and derived ejection fraction, indicating myocardial depression at equipotent light levels of anesthesia. The difference in PEP/LVET and $1/PEP^2$ between enflurane and halothane was statistically significant ($p<0.05$), with halothane appearing to be the more depressant. PEP/LVET was increased 39.3% by halothane and 14.7% by enflurane, while $1/PEP^2$ was decreased 37.6% by halothane and 22.7% by enflurane.

When N_2O was discontinued, both agents increased PEP and PEP/LVET and decreased $1/PEP^2$ and the ejection fraction. However, these changes were not statistically significant.

DISCUSSION

There have been a number of studies of the cardiovascular effects of halothane in man. Bahlman and associates[3] and Eger and coworkers[10] have shown that 1% end-tidal halothane decreases cardiac output, MAP, and total peripheral resistance (TPR) by 10 to 20%. These investigators, who used the ballistocardiogram to measure myocardial contractility, showed that the IJ wave of the ballistocardiogram was decreased by 25 to 30% with halothane. These changes were all greater with controlled than with spontaneous respirations. The depression they found at light levels of anesthesia (1%) proceeded to profound depression at

deep levels of anesthesia (2%), with the cardiac output, MAP, and IJ wave being depressed 50%.

Morrow[11] measured the effect of halothane on myocardial contractile force by suturing a Walton-Brodie strain gauge to the ventricle during cardiopulmonary bypass. Halothane (2%) administered through the oxygenator for 10 minutes decreased contractile force by 30% and MAP by 15%. Our data are consistent with the above studies, in that halothane decreased contractility, as measured by systolic time intervals, by 30 to 50% and MAP by 11%.

In contrast to halothane, there have been few studies on the cardiovascular effects of enflurane in man. These studies have shown a decreased cardiac output and MAP, with variable TPR results.[1,12] There are no previously recorded measurements of myocardial performance with enflurane in man. Our data show that at equipotent light levels of anesthesia, enflurane decreased contractility as measured by systolic time intervals consistently less than halothane. Halothane increased the PEP/LVET ratio 25% more than did enflurane.

When N_2O was discontinued in both groups, the patients appeared more lightly anesthetized. In spite of this fact, systolic time intervals showed more myocardial depression. This supports previous evidence that at light levels of halothane anesthesia, N_2O acts as a cardiovascular stimulant, probably through activation of the sympathetic nervous system.[13]

Blackburn's group[14] showed that the $Paco_2$ correlates quite well with changes in $1/PEP^2$. In their 5 patients anesthetized with N_2O and curare, a difference in the $Paco_2$ of 6 torr, as we found between the halothane and enflurane groups, produced a 15% difference in $1/PEP^2$. The $Paco_2$ difference between our 2 groups just failed to be statistically significant at the $p<0.05$ level; however, it may have been physiologically quite significant. At a lower $Paco_2$ of 40 torr, enflurane may appear to be more depressant than it did in this study.

The isovolumic contraction time used in the past to measure myocardial performance is related to the 1st heart sound, which has been shown to occur at a variable time from the onset of left ventricular contraction.[15] Recently, attention has focused on the preejection period as the interval to be measured to assess intrinsic myocardial performance. There are 4 determinants of the duration of the preejection period: (a) left ventricular contractility; (b) left ventricular end-diastolic pressure (preload); (c) aortic diastolic pressure (afterload); and (d) heart rate.

The effect of changes in heart rate on PEP was eliminated in our study by using regression formulas relating systolic time intervals to heart rate, derived by Weissler from multiple observations of both normal individuals and cardiac patients.[9]

Talley and coworkers[16] showed that PEP is only slightly affected by changes in aortic diastolic pressure, and that a change of 39 torr in the aortic diastolic pressure caused only a 7 msec (6%) change in PEP. In our study, the diastolic blood pressure decreased only 7 torr with halothane and 17 torr with enflurane and therefore should have had minimal effects on PEP.

Reitan and associates[17] reported that $1/PEP^2$ correlated well with peak ascending aortic blood flow acceleration, a good measurement of myocardial contractility, Noble and coworkers[18] having previously observed that changes in ventricular preload and afterload caused little variation in peak blood flow acceleration. Drawing from these conclusions, we feel that PEP, PEP/LVET, and $1/PEP^2$ were minimally affected by the difference in afterload in the halothane and enflurane groups.

Accepting that PEP was only minimally affected by changes in heart rate and afterload, the changes we have observed in PEP/LVET and the ejection fraction during anesthesia could reflect changes either in preload or in the inotropic state of the heart. Talley[16] showed that PEP is markedly affected by changes in ventricular end-diastolic pressure. Our study cannot separate these two factors, since measurements of the pulmonary capillary wedge pressure, left atrial pressure, or left ventricular end-diastolic pressure (LVEDP) would be needed to do this. However, if enflurane is not less depressant than halothane, our findings mean that enflurane must have raised the LVEDP more than did halothane. We do not believe this happened, since enflurane appears to produce more peripheral vasodilation and would be expected, therefore, to lower LVEDP.

Our findings probably indicate a difference in the inotropic state of the heart with

the 2 anesthetic agents. Therefore, while the lower MAP seen with enflurane is due in part to some decrease in contractility, it appears mainly due to a decrease in TPR, while the decrease seen with halothane is primarily caused by a decrease in contractility and thus by decreased cardiac output.

NEFOPAM Nefopam is an analgesic unrelated chemically and structurally to any other analgesic. Its analgesic potency is about half that of morphine. The ventilatory response to CO_2 was studied in 6 volunteers. The mean displacement to the right following 5 and 10 mg morphine was 2.98 and 3.76 torr PCO_2, respectively, while following 20 and 40 mg nefopam was 1.44 and 1.90 torr PCO_2 respectively. The difference between the drugs was statistically significant. A high incidence of nausea after nefopam may have resulted in a tendency for subjects to overventilate. *(Gasser JC, Bellville JW: Respiratory effects of nefopam. Clin Pharm Ther 18:175-179, 1975)*

Effect of P_{aCO_2} on O_2 Consumption During Cardiopulmonary Bypass in Man

RICHARD W. PATTERSON, MD*

Under conditions of anesthesia with controlled respiration, the changes in the state of the circulation due to altered P_{aCO_2} are often overlooked or attributed to the anesthetic agent. During cardiopulmonary bypass when cardiac output is kept constant, change in fluid level of the extracorporeal reservoir reflects overall change in the circulatory beds.

Following an hour on total bypass for stabilization of all parameters, a change in the oxygenator ventilating-gas mixture was induced to increase or decrease the P_{aCO_2} an average of 11 torr in 40 patients. A reduction in P_{aCO_2} from 37 to 25 torr increased mean arterial blood pressure (MAP), central venous pressure (CVP), and the volume of blood stored in the extracorporeal circuit, signifying an overall reduction in the intravascular capacity. This was associated with a decrease in total O_2 consumption ($\dot{V}O_2$). An abrupt increase of P_{aCO_2} from 26 to 37 torr produced a decrease in MAP, in CVP, and in the reservoir blood level, signifying blood "take up" by the patient. There was also an associated increase in $\dot{V}O_2$.

CARBON DIOXIDE tension affects both the blood supply[1-3] and metabolic rate,[4,5] two major determinants of the O_2 consumption ($\dot{V}O_2$) of a tissue, organ, or of the whole body. The two effects may not be concordant. For example, an increase in total body $\dot{V}O_2$ can be produced by respiratory alkalosis,[6,7] a situation which in itself selectively decreases the blood flow in several circulatory beds.[8,9]

This study, conducted during cardiopulmonary bypass in man, describes the changes in whole body $\dot{V}O_2$ and the whole body blood volume shifts that occur following a modest (11 torr) change from one CO_2 steady state to another.

METHODS AND MATERIALS

Forty patients (14 women, 26 men) in AHA classes II and III, undergoing surgical correction of acquired heart disease with the aid of total cardiopulmonary bypass, were studied. Ages ranged from 40 to 61 years and body surface area (BSA) from 1.7 to 2.2 sq m. Premedication consisted of 100 mg of secobarbital and 0.5 mg of scopolamine, given IM 60 minutes before induction. Anesthesia was induced with 200 to 450 mg of thiopental IV, and a cuffed endotracheal tube was placed after IV administration of 100 mg of succinylcholine. Anesthesia was maintained with 1% halothane in O_2.

The heart was approached through a midline sternotomy and the pericardium was opened. Venous catheters were inserted into the venae cavae through a right atriotomy. The arterial line from the extracorporeal oxygenator to the patient was inserted into the ascending aorta. A roller pump-bubble oxygenator (Bentley) provided a pump output ($\dot{Q}p$) of approximately 2.3 L/min/sq m BSA. The pump was initially primed with 1000 ml of ACD whole blood (heparin, calcium gluconate, and tris buffer added), 500 ml of lactated Ringer's, and 500 ml of 5% D/W. During the bypass interval, 1% halothane was continuously administered via a

Fluotec® vaporizer inserted in the extracorporeal oxygenating circuit. The total gas flow through this circuit varied from 10 to 14 L/min between patients but was held constant for each individual patient. Through change of water temperature in the heat exchanger, all patients were internally cooled or warmed, as measured by an esophageal thermistor placed in the midesophagus.

The ventilating gas was either 100% O_2 or a mixture of O_2-CO_2 (98:2). Switch from one to the other did not alter the total gas flow rate.

In one group of patients, bypass was initiated using the O_2-CO_2 ventilating mixture, which was continued for the entire 1st hour, during which perfusion stabilized to constant output, constant arterial and venous pressures, and constant equilibrium volume between the patient and the extracorporeal circuit. Temperature also stabilized during this time. $\dot{Q}p$ was not changed during the study period. Arterial and mixed venous blood samples were drawn from the pump-oxygenator lines, iced, and rapidly analyzed for $Paco_2$, pH, and Pao_2 by a Model 113 Instrumentation Laboratories blood-gas analyzer, with corrections made for temperature differences between patient and analyzer. From these measured values, O_2 content was derived and used in conjunction with the constant $\dot{Q}p$ to calculate O_2 consumption by the Fick equation. Subsequently, $Paco_2$ was abruptly reduced by switching the extracorporeal circuit ventilating gas to 100% O_2. Blood samples were drawn at the end of 30 minutes and analyzed as before.

In another group of patients, bypass was initiated using 100% O_2 as the ventilating mixture for the 1st hour, then switching to the O_2-CO_2 mixture.

The statistical significance of the changes in mean arterial blood pressure (MAP), mean central venous pressure (MCVP), change in bypass reservoir volume, and $\dot{V}o_2$ was determined by Student's *t*-test for paired data. The values obtained after 1 hour of constant esophageal temperature on bypass were compared with those obtained 30 minutes after the induced change in $Paco_2$.

During 6 operations in which the body temperature was maintained at a constant value for 2 hours or more, the ventilating gases were repeatedly alternated at 30-minute intervals.

RESULTS

During the bypass observation period, average body temperature of all patients was 34 (range 32 to 37 C), and the average hematocrit was 34% (range 28 to 36).

After a steady state had been established, change in $Paco_2$ resulted within several minutes in changes in MAP, MCVP, and redistribution of blood between the extracorporeal reservoir and the patient. These vascular changes persisted during the 30-minute interval until the venous and arterial blood samples were drawn.

Switching the extracorporeal gas mixture from CO_2-O_2 to 100% O_2 (table 1) produced an average $Paco_2$ decrease of 12 torr from an average baseline of 37 torr. With $\dot{Q}p$ remaining constant, MAP increased (average 23 torr), MCVP increased (average 3 torr), the volume of blood stored in the extracorporeal reservoir increased (average of 400 ml), and the total body $\dot{V}o_2$ decreased an average of 7 ml/min/sq m.

Starting from an average $Paco_2$ of 26 torr, changing the ventilating gas from a mixture containing only O_2 to one containing CO_2-O_2 (table 2) increased the average $Paco_2$ by 11 torr and resulted in a decrease in MAP, MCVP, and extracorporeal reservoir blood level (400 ml), and increased average total body $\dot{V}o_2$ 8 ml/min/sq m.

An example of values obtained in a 40-year-old man (figure) shows the repeatable changes in venous and arterial pressures, reservoir volume, and $\dot{V}o_2$ that resulted as the $Paco_2$ was altered from high CO_2 (2) to low (0) to high (2) and again to low (0) at half-hour intervals over a 2-hour period during which $\dot{Q}p$ was constant. Similar responses to changes in $Paco_2$ were observed in the other 5 patients studied for as long as 2 hours.

DISCUSSION

Study during cardiopulmonary bypass eliminated direct CO_2-cardiac effects[10] and tested the effect of CO_2 changes on the peripheral circulation and/or related alterations of body metabolism. Keeping the $\dot{Q}p$ constant throughout the observation period accentuated the overall vascular changes by eliminating the usual response of the pump running on automatic control to changes in reservoir volume or the response of the perfusionist to vascular-pressure changes. In a situation where CO_2 is being eliminated, the MABP abruptly increasing concurrently

with an increase in CVP would ordinarily prompt the perfusionist to reduce the pump flow rate, consequently restoring the pressures to original values. Switching from O_2 to CO_2, MAP decreases and the volume decreases in the reservoir, and the usual maneuver is to add volume to the system and increase $\dot{Q}p$, thus increasing the pressure. No case is included in this study that required a change in pump rate or the addition of volume expanders to compensate for changes in volume shifts or arterial pressure.

The changes described resulted from a relatively small $Paco_2$ alteration within the total range of 20 to 40 torr, the usual operating area during cardiopulmonary bypass, and demonstrate an additional determinant of the distribution of blood flow[11] and of

$\dot{V}o_2$ during bypass.[12] When $Paco_2$ was decreased and vascular redistribution occurred, blood was stored extracorporeally, an option denied the intact body, which may account in part for the failure to demonstrate the increases in $\dot{V}o_2$ reported with hypocapnia.[6,7,13]

The vascular changes due to the relative changes in $Paco_2$ are in agreement with previous investigations concerning the role of CO_2 in circulatory dynamics.[1,14,15] When $Paco_2$ was increased from the baseline of the hypocapnic situation, $\dot{V}o_2$ was increased as the patient's blood volume was expanded and perfused at low venous and arterial pressures. Vascular changes were in most instances more pronounced than the quantitative changes in $\dot{V}o_2$, and the greatest change in circulatory volume was not necessarily reflected in a similar change in $\dot{V}o_2$; this is consistent with the findings of Stainsby and Otis[16] in regard to blood flow and O_2 uptake in skeletal muscle.

DOPAMINE VS DOBUTAMINE The cardiac and systemic hemodynamic effects of dopamine and dobutamine were measured in anesthetized dogs. Dopamine increased HR only when infusion rates reached 10 μg/kg/min while dobutamine produced dose related increases between 2 and 32 μg/kg/min. Dopamine increased mean arterial pressure at infusion rates above 5 μg/kg/min while no change occurred with dobutamine at any dose. Dobutamine increased cardiac output more than dopamine. Dopamine infusions up to 10 μg/kg/min increased renal and mesenteric blood flow while dobutamine had negligible effects. These data confirm that both these sympathomimetic amines exert positive inotropic effects but cause different responses in the peripheral vasculature. *(Robie NW, Goldberg LI: Comparative systemic and regional hemodynamic effects of dopamine and dobutamine. Am Heart J 90:340-345, 1975)*

Questions and Answers

We invite you to submit questions to the Editorial Office, Kahler East, Suite C, Rochester, Minnesota 55901. The names of those submitting questions will remain anonymous if so desired.

The answers will be prepared by competent authorities, and their names will or will not appear, according to their specific wishes.

QUESTION: *Please comment on the use of $NaHCO_3$ with the administration of bank blood. I am familiar with the recommendation of Howland as to the administration of $NaHCO_3$; however, our surgeons recently have said their literature now states this is contraindicated.*

MD, Michigan

ANSWER #1: ". . . anesthetists must be ever alert to the patient as an individual with his own peculiar responses to stress. This means that rigid application of routines for management must be avoided."[1]

"The occurrence or severity of metabolic acidosis in patients requiring massive blood transfusion is not predictable; thus the routine administration of bicarbonate is not warranted."[2]

Administration of bicarbonate should be governed by the patient's acid-base status. Although Howland routinely administers 44.6 mEq of $NaHCO_3$ for every 5 units of bank blood, he states: "If blood gas studies are continuously available, sodium bicarbonate can be given only as required."[3]

If blood-gas studies are not available, the question becomes more complex. Under such circumstance, the decision to administer $NaHCO_3$ should be governed by the patient's circulatory status—that is, a warm, pink, dry patient probably doesn't need $NaHCO_3$ *empirically;* a hypoperfused patient may.[4]

The hazards of routine administration of $NaHCO_3$ during massive blood transfusion include: (1) worsening of posttraumatic alkalosis with well-known effects on the oxyhemoglobin-dissociation curve, increased myocardial irritability, and possibly vasoconstriction,[5] and (2) increased Na load in patients with sodium-retaining tendencies.

I recommend Miller's review on "Transfusion Therapy and Associated Problems," in vol 1 of the ASA Regional Refresher Courses in Anesthesiology, for a brief, concise review of the problem.

ANSWER #2: All references to blood transfusion should specify rates. Administration of 10 units of bank blood in 10 hours or in 30 minutes obviously present different situations. Also, if the patient's acid-base status can be assessed after every 5 units of bank blood, no routine administration of $NaHCO_3$ is necessary. We have attempted avoiding buffering during rapid blood replacement, as

suggested by Miller and associates,[1] and found that our patients became acidotic. The dangers of alkalinization of patients are mainly theoretic; using routinely 44.6 mEq of $NaHCO_3$ for every 5 units of bank blood, marked metabolic alkalosis does not occur.

In our last 22 patients given 32.8 ± 13.7 units of CPD blood, the pretransfusion blood level of CO_2, 26.4 ± 2.5 mEq/L, was raised at the end of transfusion (20 to 78 units) to only 31.8 ± 4.1 mEq/L, a figure only slightly elevated beyond the normal range in our laboratory (26 to 29 mEq/L). This moderate alkalosis is certainly preferable in our opinion to the dangers of acidosis. It should also be noted that there is a marked difference in the basic cardiovascular status of young servicemen and middle-aged and elderly cancer patients.[2]

QUESTION: *Kindly advise me on the usefulness of preoperative determination of blood volume.*

MD, Massachusetts

ANSWER #1: Blood-volume measurements, forgotten in many hospitals, are extremely useful in the management of selected patients undergoing surgical procedures. At Memorial Hospital we recommend that initial baseline measurements be done in those patients in whom:

1. Unusual blood or fluid loss can be expected during surgical intervention.
2. Cardiac insufficiency or metabolic disturbances result in body fluid imbalance.

If circulatory instability then ensues during the hospital stay, subsequent determinations are an aid in patient management.

Blood-volume measurements are not universally accepted, however, as essential in patient care. There are several reasons for this:

1. Many clinicians feel that if they are able to measure central venous pressure (CVP) and monitor urine output, they are able to control most acute situations. It is entirely possible, however, for a heart to fail in association with a contracted blood volume. The rising CVP and decreasing urine output may then be misinterpreted.

2. A common criticism is that blood-volume measurements are inaccurate, especially those done with plasma tags. We found that they are highly reproducible if scrupulous attention is paid to technic.

3. Tracer loss with blood or plasma can be a problem during acute situations. This problem, too, can be lessened to some extent if samples are drawn at 10, 15, and 20 minutes and results extrapolated to zero time.

4. Isolated blood-volume measurements are of questionable help in that obesity, weight loss or gain, extremes of age, and sex alter so-called normal values. For that reason, we feel it is essential to do serial determinations, starting with a baseline if possible, in our complicated fluid-balance problems.

Although the usual surgical patient can be managed by monitoring vital signs, urine output, and CVP, blood-volume measurements are important in caring for patients with extraordinary fluid and circulatory problems.

* * *

ANSWER #2: One major advantage of preoperative blood-volume measurement is definition not only of total circulating blood volume but also quantification of the plasma and red-cell fractions, giving more information than just hemoglobin and hematocrit determinations. For example, low hemoglobin and hematocrit values can be associated with a high blood volume composed of a normal red-cell volume and a high plasma volume. Thus the apparent anemia indicated by a low hemoglobin value is misleading. Second, by knowing the actual preoperative

plasma and red-cell volumes, the adequacy of transfusion can be checked postoperatively against an accurate standard for each individual patient. This allows additional transfusion therapy with the most appropriate blood component, reducing the risk to the patient of overtransfusion and exposure to blood-group antigens. Just as important, it allows more efficient use of blood-bank resources.

QUESTION: *A 65-year-old hypertensive patient is on diuretic therapy and in generally good health. Potassium is 3 mEq/L (normal = 3.5 to 5 mEq/L). He is having an elective herniorrhaphy. Please indicate management if: (a) Patient is seen in the operating room just before proposed operation (when K^+ results have just come back); (b) On preoperative rounds the night before operation; (c) Several days prior to proposed operation. Would a K^+ of 2.5 mEq/L alter your management? How would you manage a patient with low K^+ for emergency surgery? Should all patients on diuretic therapy have preoperative electrolytes determined?*

MD, Georgia

ANSWER #1: Chronic diuretic therapy with K^+ depletion presents a serious hazard to the patient on digitalis therapy and occasionally when the need arises to reverse the action of muscle relaxants. A rigid approach to this predicament is impossible; we can only propose certain useful guidelines. Serum electrolyte concentrations are at best a poor guide to the magnitude of K^+ depletion.

Total body potassium content in the human adult is approximately 4000 mEq, of which 1% is in the extracellular compartment.[1] Enormous deficits may accrue with a relatively small decrease in serum K^+, which emphasizes the difficulty encountered in the evaluation of potassium balance. Although some anesthesiologists may succumb to the temptation and cancel the planned operation in circumstances described under (a), such a unilateral move is not necessarily warranted or useful. First, a decision as to replacement therapy must be formulated clearly if the patient is to be anesthetized at a future date. Clearly, an objective evaluation of K^+ repletion requires close measurement of potassium intake and output, a project not recommended for routine use. Given the conditions described, a patient in good health who requires an elective herniorrhaphy and whose serum K^+ is 3 mEq/L can be operated on under regional or general anesthesia. If there is concern regarding fluctuations in the serum K^+, samples may be drawn during and immediately following operation. Potassium is a potentially lethal drug. In a non-digitalized patient and in the absence of cardiac arrhythmias I prefer not to start replacement therapy while the serum K^+ has decreased to 2.5 mEq/L.

Unfortunately, even under ideal conditions, most laboratories will not report results back in less than 60 minutes, thereby making acute replacement difficult. If desired, additional K^+ can be administered IV as KCl solution at a rate not to exceed 0.2 mEq/kg/hr through a central venous line. (Potassium solutions must never be administered through a peripheral IV).

If the patient is seen several days before operation, an increase in oral K^+ replacement is advisable. Such therapy is best not carried out for more than 2 to 3 days, as it has been known to result in intestinal ulceration.

If the serum K^+ is below 2.5 mEq/L or emergency surgery is required, an IV infusion is in order, as indicated above, followed by repeated measurements of serum K^+ at 2-hour intervals until the concentration has stabilized in the normal range. Although objective reasons can be listed why any one mode of anesthesia is to be preferred over another, the choice is generally subjective, and good data on morbidity are unavailable.

Digitalis toxicity and emergency surgery are not an infrequent combination. In this setting, anesthetics should be chosen carefully, in view of the propensity to lethal cardiac arrhythmias during transient episodes of hypokalemia. Except for the patient with massive burns, extensive muscle wasting secondary to neurologic disease, chronic renal failure, or acute metabolic acidosis following circulatory arrest intraoperatively, hypokalemia is more common than appreciated.

Intraoperative monitoring of serum K^+ is not yet considered a routine procedure in the critically ill except for open-heart surgery. Until such time that these measurements will be available, it is likely that disturbances of cardiac rhythmicity during

emergency operations may not be recognized as being secondary to hypokalemia.

* * *

ANSWER #2: The case presents a difficult clinical question. While it would be generally agreed that severe hypokalemia increases the incidence of cardiac arrhythmias, the risk of moderate levels of hypokalemia combined with the pharmacologic and physiologic trespass of anesthesia and surgery is not well established. Levels of serum K^+ not hazardous in the unanesthetized patient may cause serious problems during anesthesia. Acute changes in serum K^+ occur in response to commonly used anesthetic agents and neuromuscular-blocking drugs.[1,2]

Respiratory alkalosis and acidosis during anesthesia can effect serum K^+ and may initiate cardiac arrhythmias.[3] Low extracellular K^+ and the resultant increased rate of diastolic depolarization[4] may potentiate, or increase in frequency, ventricular arrhythmias, which occur commonly during anesthesia. Whether the hazard of arrhythmia is due to the low serum K^+, total body potassium depletion, or to an abnormal ratio of intracellular:extracellular K^+ is not clear.

However, even a small risk of increase in potentially hazardous cardiac arrhythmias indicates delay in elective surgery to permit replacement therapy, allowing adequate time for equilibration, particularly in patients who have a history compatible with total body potassium depletion.

Therefore, in this patient with vascular disease and on chronic diuretic therapy, it would be wise to postpone elective surgery to allow for replacement therapy even though hypokalemia is recognized shortly before scheduled operation. We prefer to use an oral replacement with a liquid preparation of KCl, with which it is usually possible to correct moderate hypokalemia in 24 to 48 hours. A repeat serum K^+ and an ECG rhythm strip should be obtained to ascertain adequacy of treatment prior to proceeding with the operation.

Although it is not possible to adequately set limits of serum K^+ for elective surgery, we have used 3.2 mEq/L as an accepted level in otherwise healthy patients without ECG evidence of hypokalemia. However, clinical judgment must prevail in these borderline cases, since definitive safe levels have not been established.

In a patient scheduled for emergency surgery, K^+ depletion should be corrected prior to operation, when possible, as should other electrolyte and acid-base abnormalities, always weighing the risk of delay against the urgency of the surgical procedure. ECG monitoring should accompany attempts to rapidly replace K^+ by the IV route.

Since most diuretic therapy leads to increased K^+ excretion and potentially to K^+ depletion, patients on diuretic therapy should have preoperative electrolyte determination.

QUESTION: *. . . but for the (extremely rare) absolute contraindications, and (or) the "stonewall" resistance of an occasional patient to a regional, and (or) the lack of skill on part of the anesthesiologist necessitating it, is there any place for general anesthesia for adults in this day and age replete with knowledge of its (GA) dangers?*

MD, Illinois

ANSWER #1: Upon reflection of the many serious general anesthesia problems whose etiology and significance is unknown (malignant hyperthermia, "halothane hepatitis,"

trace elements of anesthetic agents, hyperkalemia-trauma-succinylcholine, abnormal pseudocholinesterases, irreversible pancuronium, "dual block," to enumerate a few), perhaps it is logical to seriously consider the relative merits of regional versus general anesthesia in adults.

It is well confirmed that properly administered peripheral nerve block for surgical anesthesia has the advantage over general anesthesia in that it does not upset general body physiology, e.g., depressed respiration, hypotension, cardiac arrhythmias, nausea, vomiting and regurgitation, and oliguria. By carrying pain relief into the postoperative period, peripheral nerve block decreases the need for narcotics, with their respiratory depression and complications. Because of the safety of regional anesthesia and the problems associated with general anesthesia, it would seem that, objectively, regional anesthesia should be chosen unless general anesthesia is specifically indicated.

Other than for the reasons enumerated in the question, I believe that general anesthesia is "indicated" for open-chest surgery, particularly cardiopulmonary bypass or coronary grafts. Patients with severe angina may be poor candidates for regional anesthesia because of the fine line between apprehension and (or) angina and depression from "sedation." According to Smith and Wollman,[1] general anesthesia seems to improve tolerance to cerebral ischemia, so that it might be preferred for carotid endarterectomy, although this is debated in vascular surgical circles.[2]

In summary, I would prefer to reword the question to say, "In this day and age with knowledge of general anesthesia dangers, does general anesthesia deserve the place it now holds in routine anesthesia practice (approximately 85% of the anesthesia is general)? The answer to that question is a resounding NO!!!

L. Donald Bridenbaugh, MD
Department of Anesthesiology
Mason Clinic
Seattle, Washington

2. Rainier WG, Guillen J, Bloomquist CD, et al: Carotid artery surgery: morbidity and mortality in 257 operations. Am J Surg 116:678-681, 1968

ANSWER #2: It is hardly appropriate to relegate general anesthesia to a category of being used only if regional anesthesia is contraindicated or impossible. Over the last 25 years, we have been fortunate in having had a variety of new general anesthetic agents developed. As a devotee of both regional and general anesthesia, I think we are fortunate to have such a wide repertoire of technics and agents available for our use. The anesthetic management of a patient should be tailored to fit the whole patient's needs, both surgical and psychological. With our extensive armamentarium of both general and regional anesthetic agents and technics, this is possible.

The questioner implies that the dangers of general anesthesia are greater than those of regional anesthesia. Documentation of this is lacking. Anecdotal reports can be found for each side of this question, but truly significant comparative studies have not been reported.

Operations on the upper extremities and distal to the diaphragm may be easily and relatively simply managed with regional anesthetic technics in the appropriate patient. Most other surgical procedures become a "tour de force" for regional anesthesia and are better managed with a general anesthetic.

Slightly over 50% of the anesthetics in the United States are administered by nurse anesthetists. It would be logistically impossible at this point to train nurses in the technics of regional anesthesia.

Finally, the patients in this country are accustomed to the concept of general anesthesia for surgical operations. This is a potent psychologic force which would be extremely difficult to overcome. To overcome this attitude, if this were desirable, would require a generation or more.

In summary, considering the operation to be performed, the mental attitude of the patient, the training and capabilities of the anesthetist, and the prejudices of our medical and surgical colleagues, there will always be room for both regional and general anesthesia. Only with this attitude are we able to make the anesthetic fit the patient's needs, rather than vice versa.

The Effects of Doxapram on Cerebral Blood Flow and Peripheral Hemodynamics in the Anesthetized and Unanesthetized Goat

DAVID J. MILETICH, PhD*
ANTHONY D. IVANKOVICH, MD†
RONALD F. ALBRECHT, MD‡
ROGER F. BONNET, MD§
CHARLES R. REIMANN, MD‖
Chicago, Illinois**

The effects of doxapram on cerebral blood flow (CBF) and peripheral hemodynamics were evaluated in the goat after direct injection into the cerebral circulation and after peripheral IV administration. Doxapram injected centrally via the temporal artery, in doses too small to affect peripheral circulation, produced an immediate and prolonged decrease in CBF in both anesthetized and unanesthetized goats. The reduction in CBF was considered not to be due to changes in blood CO_2 concentration, since blood flow decreased immediately after injection and as reduction in CBF occurred in the absence of changes in blood CO_2.

Peripheral IV administration of doxapram in clinical doses to anesthetized and unanesthetized goats produced a biphasic cardiovascular response. Cerebral blood flow, cardiac output, blood pressure, and heart rate decreased abruptly, but with the exception of CBF, these parameters returned to or exceeded preinjection values within 30 seconds. Cerebral blood flow slowly returned to preinjection values (within 10 minutes) and, in the case of unanesthetized animals and anesthetized animals ventilated with room air, rose substantially above preinjection levels, reaching a peak 20 minutes after injection. The latter observation is thought to be a compensatory reaction to the reduction in CBF; it was not evident in anesthetized animals ventilated with 100% O_2.

REPORTS concerning the use of doxapram in both man and animals have indicated that this agent initiates cardiovascular alterations, characterized by moderate increases in blood pressure, heart rate, and cardiac output.[1-4] In most instances, cardiovascular changes due to doxapram administration appear tolerable in view of the clinical benefit from its use. However, it has been demonstrated that prolonged oral administration of doxapram to dogs produces petechial perivascular hemorrhages in brain tissue similar to the hemorrhage seen after ischemic hypoxia.[5]

Funderburk and associates[6] concluded that doxapram did not possess direct cerebral vasoactivity but influenced cerebral blood flow (CBF) secondary to its effect on respiration and blood gases. Contrary to this conclusion, we have observed that doxapram abruptly decreases CBF in both anesthetized and unanesthetized goats in a way not related to changes in blood gases. It

Paper received: 2/24/75
Accepted for publication: 8/5/75

was the purpose of this study, therefore, to simultaneously evaluate the effects of doxapram on CBF, blood gases, and cardiovascular hemodynamics, in order to gain a better understanding of the way in which doxapram influences cerebral blood flow.

METHODS

The studies were performed with a recently developed animal model for the continuous measurement of ipsilateral hemispheric CBF in the unanesthetized, unrestrained goat. We confirmed the validity of this approach for the study of CBF by the technic of radioactively labeled microspheres.[7] Anatomic description of the goat cerebral vasculature and methodology employed have been described elsewhere.[8,9]

Briefly, total blood flow to each hemisphere is provided by a single external carotid artery. The external carotid bifurcates extracranially, forming the lingual and internal maxillary arteries. Two major vessels, the ramus anastomoticus and arteria anastomotica, arise from the internal maxillary and enter the cranial vault, where they empty into the rete mirabile. Branches from the internal maxillary also supply blood to the extracerebral tissues via the buccinator, ethmoidal, and ophthalmic arteries. The rete mirabile consists of a compact network of intertwined, freely anastomosing arteries.

In the goat, a high degree of contralateral communication exists across the midline of the brain between each side of the rete. The vascular communication is so extensive that the two structures are virtually one. However, physiologic separation is maintained when the blood pressure in each side is equal. Abnormally low blood pressure in one rete incurs blood flow from the opposite rete, thus maintaining adequate blood flow to each hemisphere. In the goat, the vertebral arteries do not contribute to the cerebral blood supply.

Ten mature female goats weighing 30 to 40 kg were surgically prepared for study as described by Reimann's group.[9] Anesthesia was induced with mask-administered halothane after which the animal was intubated; artificial respiration was maintained by an Ohio respirator with 1.5% halothane in 100% O_2. An esophageal gastric tube was inserted to prevent vomiting and aspiration. A lateral incision was made along either the right or left mandible and a small portion of the mandible was removed to expose the internal maxillary, ramus anastomoticus, temporal, and dental arteries. Ligatures were placed around the internal maxillary distal to the ramus anastomoticus and on the temporal and dental arteries. Blood flow through the ophthalmic, ethmoidal, and buccinator arteries was obliterated by slowly injecting 1 to 2000 NIH units of thrombin in 0.5 ml of saline solution into the internal maxillary artery anterior to the site of ligation. The injected thrombin produced immediate clotting, as was evident by the appearance of thrombosed vessels in the sclera and postsurgical ipsilateral blindness. An electromagnetic flow probe was then placed around the internal maxillary. After this, under direct vision, a small catheter was placed into the temporal artery and advanced a distance of approximately 0.5 cm to the juncture of the temporal and maxillary arteries. Care was taken to avoid projection of the tip of the catheter into the maxillary artery. The catheter and leads from the electromagnetic flow probe were then externalized and secured to the goat's horn. The incision site was appropriately closed for proper healing.

Following this procedure, a right thoracotomy was performed and an electromagnetic flow probe was placed around the pulmonary artery for the measurement of cardiac output. Chronic femoral artery and venous catheters were then implanted. After completion of the surgical procedure, the animals were permitted to recover for at least a period of 1 week to 10 days before study.

Upon recovery, the animals were given doxapram either in small doses (4 mg) via the temporal artery catheter or IV via the femoral venous catheter in recommended clinical doses (1 mg/kg). The goats were studied in both the awake and halothane-anesthetized (usually 1.5%/100%) state. In the anesthetized animals, respiration was controlled by an Ohio anesthesia ventilator. Paralysis was induced when necessary by succinylcholine. Arterial blood samples were drawn at various intervals after doxapram injection for blood-gas analysis. Cerebral blood flow and cardiac output were continuously measured with a Statham electromagnetic flowmeter (model 2200).

Statistical significance of blood-gas changes following doxapram was determined by one-way analysis of variance. Significance of other parameters was evaluated under the null hypothesis, assuming an equal opportunity for no change, an increase, or a decrease in any parameter following doxapram.

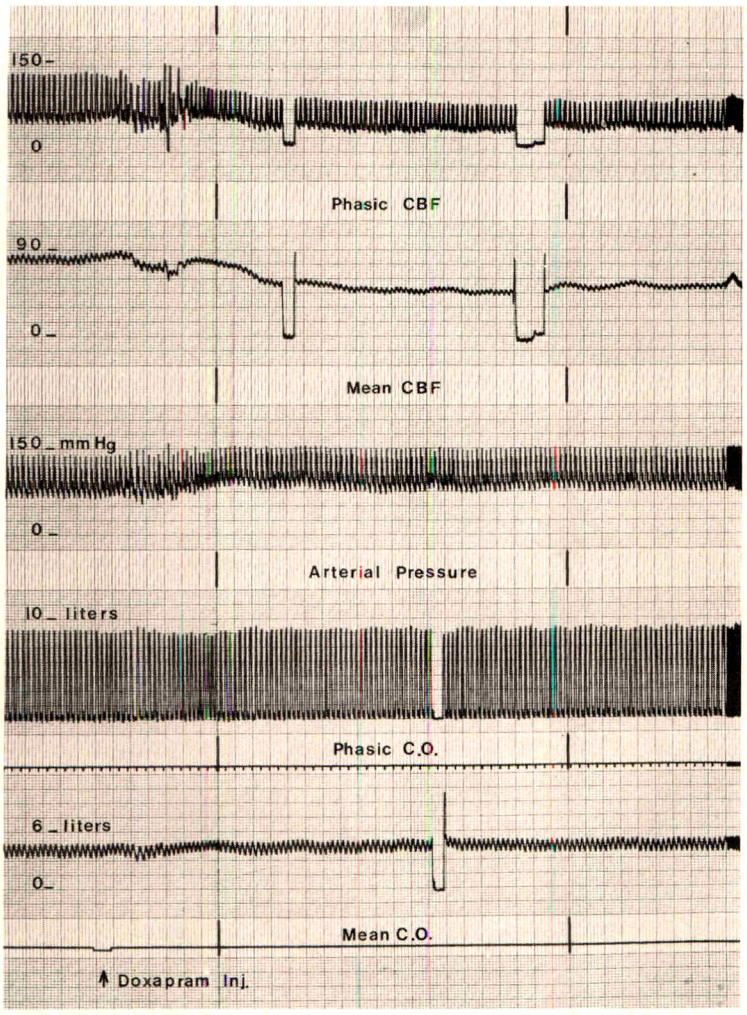

FIG 1. Typical cardiovascular changes in the unanesthetized goat after temporal artery injection of 4 mg of doxapram. Paper speed 2.5 mm/sec. ICBF = ipsilateral cerebral blood flow in ml/min, CO = cardiac output in L/min.

The probability of any situation occurring consecutively in multiple independent trials was therefore the product of its individual probability.

RESULTS

Figure 1 shows the effects of a bolus injection of doxapram (4 mg in 0.4 ml) via temporal artery catheter into the cerebral circulation of the unanesthetized goat. Within 6 seconds after injection, CBF began to decrease abruptly and arterial blood pressure and cardiac output rose slightly. These effects were typically seen in both unanesthetized and anesthetized animals. The doxapram-induced reduction in CBF was somewhat attenuated in the halothane-anesthetized animals (table 1). Halothane, a cerebrovascular vasodilator, may have opposed the vasoconstrictive effect of doxapram during anesthesia.

The hemodynamic alterations caused by a peripheral IV injection of doxapram (1 mg/kg) in an artificially ventilated, anesthetized goat are shown in figure 2 and summarized in table 2. Immediately after injection, CBF, arterial blood pressure, heart rate, and cardiac output dropped sharply. Generally, all parameters returned to or exceeded preinjection values after 3 minutes except for CBF, which in every case remained below preinjection values for a considerably longer period (6.2 ± 2.4 minutes; mean ± SD). Blood gases, particularly CO_2, did not fluctuate significantly during this period (table 3). Intravenous administration of doxapram (1 mg/kg) produced similar

TABLE 1
Reduction in Ipsilateral Cerebral Blood Flow After Central Administration of Doxapram (4 mg) in the Anesthetized and Unanesthetized Goat

	Anesthetized	Unanesthetized
Control ipsilateral CBF	93 ± 18 ml/min	75 ± 13 ml/min
30 sec (post-injection)	74 ± 6*	67 ± 14*
1 min (post-injection)	72 ± 6*	62 ± 11*

*Mean % ± SD of control values, $p < 0.05$; n = 18.

hemodynamic changes in unanesthetized and anesthetized goats (table 2).

In addition to the "early" cardiovascular changes seen after IV doxapram administration, within 10 minutes postinjection, CBF was seen to increase above preinjection values in unanesthetized animals (fig 3A) and in anesthetized animals ventilated with room air (fig 3B). This increase was generally seen 15 to 20 minutes after injection and may have been a compensatory response to the prior CBF reduction. Anesthetized animals ventilated with 100% O_2 exhibited only a slight increase in CBF (fig 3C). In unanesthetized animals, blood CO_2 concentrations at 20 minutes were lower than preinjection levels and therefore could not account for the elevated CBF seen in these animals (table 4).

DISCUSSION

In this study, the hemodynamic effects of IV doxapram and doxapram injected directly into the cerebral circulation of anesthetized and unanesthetized animals were evaluated. Immediately after injection, arterial blood pressure, cardiac output, heart rate, and CBF decreased abruptly. Approximately 30 seconds after injection, these parameters returned to preinjection values and in

some instances rose above control values, with the exception of cerebral blood flow, which returned to preinjection levels after several minutes. These changes in CBF were not due to fluctuations in blood gases, since respiration was controlled and CO_2 levels held constant. Peripheral cardiovascular changes may have contributed to the early decrease in CBF, but peripheral hemodynamic parameters returned to normal or greater values long before cerebral blood flow. In addition, small doses of doxapram injected directly into the cerebral circulation via the temporal artery produced reductions in CBF identical with those seen with clinical IV doses, but without peripheral cardiovascular manifestations.

The effects of doxapram on CBF and peripheral hemodynamics in the unanesthetized animal were similar to those seen in anesthetized animals with one important exception. In the unanesthetized animal, CBF exhibited a protracted biphasic response. Immediately after the period of reduced flow, CBF rose gradually until above the preinjection level. It remained elevated for as long as 30 minutes in some instances before returning to predoxapram levels. This pattern of blood flow is suggestive of the hyperemic response seen in tissues and organs following O_2 deprivation during a period of reduced flow.

Anesthetized animals may not have responded in this fashion because they were ventilated with 100% O_2 and were not subjected to hypoxia as a result of the reduced cerebral blood flow. Supporting this hypothesis is the observation that CBF in anesthetized animals ventilated with room air behaved much as that in unanesthetized animals after doxapram injection. That these changes in CBF were not the result of changes in arterial blood CO_2 is evident from the fact that when CBF was elevated, CO_2 concentrations were below predoxapram values. However, it is possible that brain tissue concentrations of CO_2 built up during the period of reduced CBF could have elicited the subsequent cerebral vasodilation.

It is not possible from the data presented

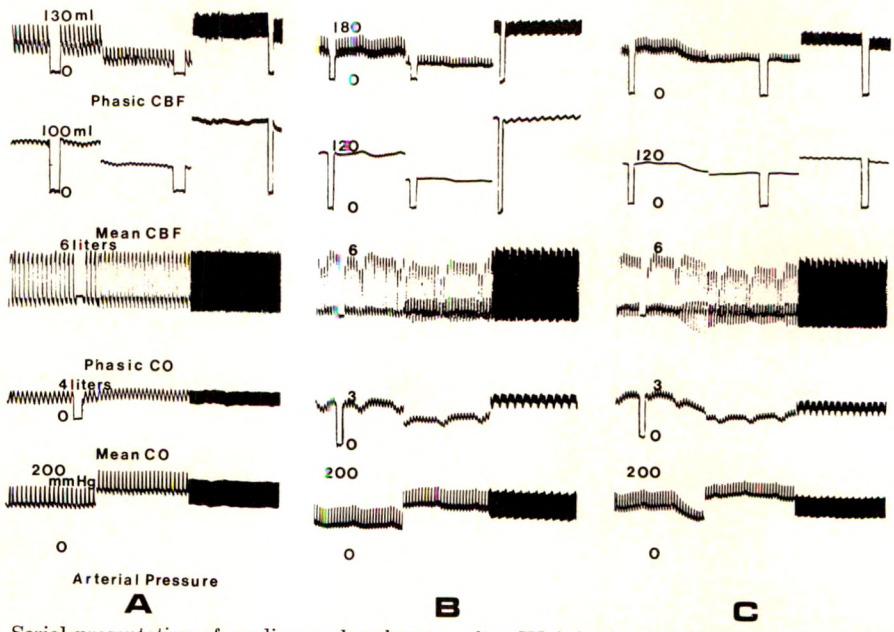

FIG 3. Serial presentation of cardiovascular changes after IV injection of doxapram (1 mg/kg). First panel in each series represents preinjection values; 2nd panel, the lowest point of CBF decrease (2 to 3 min after injection); 3rd panel, the highest point in CBF increase (15 to 20 min after injection). A, unanesthetized goat; B, anesthetized goat ventilated with room air; C, anesthetized goat ventilated with 100% O_2. Paper speed 2.5 mm/sec in 1st two panels of each series and 0.4 mm/sec in 3rd panel of each series. ICBF = ipsilateral CBF in ml/min, CO = cardiac output in L/min.

here to distinguish the mechanism or mechanisms by which doxapram produced peripheral cardiovascular depression and stimulation in both anesthetized and unanesthetized animals. A recent study has shown that doxapram is a nonselective medullary stimulant.[10] Perhaps doxapram stimulates cardioregulatory regions in the brain as well as in areas involved in respiration. However, arguing against this is the observation that small doses injected directly into the cerebral circulation produced only mild peripheral hemodynamic changes.

The findings of this study directly contradict those previously reported,[6] that doxapram produces cerebral vasoconstriction indirectly by inducing hyperventilation and lowering blood CO_2 concentrations. Our data indicate that doxapram constricts the cerebral vasculature in a way unrelated to changes in blood gases and peripheral hemodynamics. It should be noted that the former study was based upon observations made in only two animals, and that blood flow in only a small area of the cortex of each animal was evaluated, factors that place severe restraints upon interpretation of the results. In addition, species difference could account for the variance of results seen between our data and those previously reported.

The clinical significance of the effects of doxapram in the goat is at this point speculative. If CBF is reduced in humans when doxapram is administered, there may be a greater amount of O_2 extracted from each milliliter of blood perfusing the brain and no change in net O_2 uptake or availability. There is, however, a limit to the ability of the brain to compensate for decreases in perfusion by increased O_2 extraction.[11] It is possible that, in some patients, such a decrease in CBF will result in a critical decrease in available O_2, particularly in marginally oxygenated or anemic patients.

BLOOD GAS VALUES Gas tensions in blood withdrawn from a Swan-Ganz catheter in the proximal pulmonary artery and wedge position were compared. Blood gas tensions from the wedge position, but with the balloon deflated, varied greatly. A high percentage of these samples were similar to the mixed venous (pulmonary artery) samples reflecting the high incidence of nonventilated lung areas in critically ill patients. This finding also emphasizes the fact that a Swan-Ganz catheter may be properly placed but unsaturated blood still obtained when used in patients with atelectasis. The high O_2 tension in samples from the wedge position may result from admixture of pulmonary capillary blood during sample withdrawal and/or diffusion of alveolar gases through the walls of small pulmonary arteries. Using this false high O_2 partial pressure would result in errors in calculated O_2 content used in the Fick determination of cardiac output and right-to-left shunt. Blood samples from Swan-Ganz catheters should be withdrawn slowly (3 ml/min) and results interpreted cautiously. Criterion for proper wedge position should no longer include aspiration of saturated blood especially in patients with lung disease. *(Suter PM, Lindauer JM, Fairley HB et al: Errors in data derived from pulmonary artery blood gas values. Etomidate: An Ultrashort-Acting Nonbarbiturate Agent for Anesthesia Induction

JOHN M. GOODING, DO*
GUENTER CORSSEN, MD†
Birmingham, Alabama‡

Clinical evaluation of etomidate, an ultrashort-acting nonbarbiturate hypnotic agent, shows it to be useful for anesthetic induction in adults. It produces sleep in 1 arm-brain circulation time, metabolites apparently peaking at 7 minutes postinjection. Cardiovascular and respiratory systems appear minimally affected and there is no indication of organ toxicity or other biochemical or hematologic drug-induced disturbances. Moderate pain on injection at some sites and transient myoclonia were the principal disadvantages observed.

INDUCTION of general anesthesia involves 2 personal viewpoints, not necessarily conflicting: The patient wants to go to sleep comfortably—what matters most to him is a rapid and pleasant induction. The anesthesiologist, too, values the advantage of speedy onset of sleep, but his first concern is for the safety of his patient with respect to the drug used.

Because the hypnotic agents now available are often associated with significant adverse effects, the search continues for the "ideal" nonbarbiturate drug whose duration of action is ultrashort. Recently, Janssen,§ studying a series of compounds related to imidazole-carboxylate, found the ethyl-methylbenzyl-imidazole-carboxylate, etomidate, to offer distinct advantages over other induction agents tested.

Etomidate (figure) is water-soluble and is provided as the sulfate. It produces sleep in a single arm-brain circulation time. Since its breakdown to inactive metabolites takes place through hydrolysis, its short duration of action does not depend solely on redistribution. The hydrolysis, affecting the ethyl-ester side chain takes place in both the blood and the liver.[1]§ Metabolites reach a peak 7 minutes after injection and are inert

with respect to sedative properties.[1*] The cardiovascular and respiratory systems appear minimally affected, and there is no indication of organ toxicity or other biochemical or hematologic drug-induced disturbances.[1*] Etomidate does not cause detectable histamine release.[2]

Published reports[1,3,4] on the clinical use of etomidate as an intravenous induction agent showed enough pharmacologic advantages to warrant our further clinical investigation in human volunteers.

METHODS

The series included 48 male and female surgical patients, aged 18 to 75 (mean 45.9) years, in a predetermined randomized order of 3 types of premedicants, 2 hypnotics, and 2 speeds of injection. For each case informed consent was obtained. Premedication, administered intramuscularly 15 to 45 minutes before induction of anesthesia, consisted of 0.5 mg of atropine, 0.1 mg of fentanyl with 0.5 mg of atropine or 10 mg of diazepam with 0.5 mg of atropine. Anesthesia was induced with sodium thiopental (4 mg/kg IV) or etomidate (0.3 mg/kg IV). Speed of injection was either 30 or 60 seconds, and the injection site was either the dorsum of the hand or the antecubital fossa. Concurrent medications were noted but not discontinued.

During administration of the induction hypnotics and for 3 minutes afterward, the following determinations were recorded: systolic and diastolic blood pressure (inflatable cuff), heart rate (ECG), hypoventilation or apnea, involuntary movements, and pain at the injection site. Each patient was observed during the operation and immediately afterward, and follow-up visits were made 24 and 48 hours after operation. All values were subjected to computerized statistical analysis.

RESULTS

Systolic blood pressure after thiopental induction was reduced by 15 torr and after etomidate by 5 torr. No change in diastolic pressure was noted with either hypnotic agent. Heart rate increased 6 beats per minute after thiopental but did not change with etomidate. The cardiovascular differences were not statistically significant.

With etomidate, slight myoclonia developed in 25% of the patients and severe myoclonia in 8% (significance borderline); all were of brief duration. There was no instance of myoclonia among patients receiving thiopental, and no severe myoclonia among etomidate subjects who had received diazepam or fentanyl as premedication.

Pain on injection was noted in 37% of the etomidate group, all of whom had the injection site on the dorsum of the hand; no patient experienced pain when an antecubital vein was used. The incidence of pain was higher at the 60-second injection speed than at 30 seconds. With respect to premedication, 50% of patients receiving atropine alone experienced venous pain, whereas the incidence was 38% with fentanyl and atropine and 25% with diazepam and atropine. In 1 patient, chemical phlebitis followed etomidate induction; the condition lasted less than 24 hours. No patient receiving thiopental experienced pain on injection or developed phlebitis.

With etomidate induction, hypoventilation occurred in 25% of the patients and transient apnea was noted in 16%. Persistent apnea occurred only following thiopental (96%) necessitating controlled ventilation and subsequent intubation. Neither the speed of injection nor the type of premedication showed any correlation with respiratory depression.

DISCUSSION

Etomidate appears to meet many of the requirements for an optimal induction agent, particularly with respect to duration of action and effects on cardiovascular function.

Janssen* and others[1,3-5] have reported the heart rate to be not affected, or increased only slightly and for a short time. Systemic vascular resistance appears to be reduced and cardiac output and stroke volume increased.[3,4] Myocardial O_2 consumption is reduced;[3,4] myocardial contractility is not significantly impaired.[5] In our series, there was no significant difference in cardiovascular function with either hypnotic agent used. Systolic and diastolic blood pressure remained stable; heart rate increased slightly with thiopental but not with etomidate.

One significant adverse effect of etomidate is the occurrence of involuntary movements. The origin of such motion is thought to be disinhibition of uncoordinated brainstem

*Janssen Pharmaceutica.

activity,[6] the incidence having been reported to be as high as 25%.[1] Rarely, however, are the involuntary movements intense enough to be troublesome. In one study involving 100 cases undergoing etomidate induction, only 4 instances of involuntary movements were of clinical importance, and these were transient.[1] Marked myoclonia has been precipitated by physical contact with the patient during drug administration,[1] the incidence of myoclonia reportedly being reduced by premedication with diazepam and the use of higher doses of etomidate.

None of the instances of severe myoclonia occurred in patients who had received diazepam or fentanyl premedication, and in no case did the involuntary movements persist beyond the 1st minute after injection.

Another reported disadvantage of etomidate is pain at the site of injection, particularly in the dorsum of the hand.[1] The importance of the injection site was confirmed in our series; pain did not occur when a proximal vein was used. It is intriguing that the incidence of such pain was lower with diazepam than with fentanyl premedication. Our negligible incidence of phlebitis is in accord with findings elsewhere.[1]

Being a purely hynotic agent, etomidate lacks analgesic properties. When pain is present or anticipated, this agent should be accompanied by an appropriate analgesic drug.

Complementing the advantage of cardiovascular stability is the drug's short duration of action—resulting, as noted by Janssen and others,[1]* from hydrolysis of its ethyl-ester side chain. In one published study,[6] subjects were alert and able to talk 8 minutes after injection. Sedation may be prolonged with higher doses, repeated doses, or with long-acting premedication.

Induction is as rapid as with thiopental.[1] Maximum brain levels are said to be reached within 1 minute after injection.*

Respiration is affected but not to the extremes commonly seen with thiobarbiturates. Transient hypoventilation is usually the most common adverse respiratory effect. Short-lasting apnea has been reported in as many as 12% of cases,[1] with the subjects resuming spontaneous breathing within 90 seconds.

*Janssen Pharmaceutica.

The apnea noted in 16% of our patients receiving etomidate was transient, spontaneous ventilation returning within 2 minutes. Since the subjects were allowed to breathe O_2 before and during induction, ventilatory assistance was not required. Only after thiopental was controlled ventilation and subsequent intubation necessary. Transient hypoventilation was more common in the etomidate group, affecting 25% of the patients. The speed of injection and type of premedication did not affect the incidence of respiratory depression with either hypnotic.

Since etomidate has not been associated with detectable release of histamine,[2] reactions such as profound hypotension, urticaria, or bronchospasm should not occur as clinical problems.

Patients described etomidate induction as pleasant, and there appeared to be adequate amnesia. There were no reports of "hangover" or headache. Etomidate induction appears to be compatible with any type of maintenance anesthesia. No instances of hallucinations or psychotic experiences occurred during the awakening period.

In our series, etomidate was well accepted by both patients and anesthesiologists. In view of its pharmacologic properties, one might expect its beneficial use in emergency and cardiovascular surgery, in 1-day surgery and short surgical procedures, in high-risk patients, in patients with anticipated airway problems, and in anesthesia for diagnostic and elective procedures, such as cardioversion. Further study is needed to establish the role of this agent in these and other conditions involving the induction of other types of general anesthesia than those described herein.

ACKNOWLEDGMENT

The authors wish to express their appreciation to Dr. David C. Hurst, Professor and Chairman of the Department of Biostatistics, for his valuable help.

ENDOTRACHEAL ANTIBIOTICS Gentamicin or aminosidin plus polymyxin B was administered into the tracheas of patients with tracheostomies 3 times daily. Positive cultures of bronchial secretions occurred in 47.7 and 53.1% of patients respectively. However, there was a difference in the nature of the offending organism in the 2 groups. Klebsiella was recovered from 28.8% of the specimens obtained from patients who received gentamicin and in only 5.9% of those from aminosidin-polymyxin treated patients. Pseudomonas aeruginosa and pneumococci were found more frequently in the aminosidin/polymyxin than gentamicin group but the differences were not statistically different. The administration of aminosidin/polymyxin was associated with a transient irritative cough in some patients. *(Klastersky J, Hensgens C, Noterman J et al: Endotracheal antibiotics for the prevention of tracheobronchial infections in tracheotomized unconscious patients. A comparative study of gentamicin and aminosidin-polymyxin B combination. Chest 68:302-306, 1975)*

PULMONARY EDEMA Thirty-seven critically ill patients with suspected hypovolemia received an intravenous fluid challenge. Twenty-one patients receiving primarily colloid solutions manifested slightly elevated left ventricular filling pressures but normal plasma colloid osmotic pressures. None of these patients developed pulmonary edema. Eleven patients receiving primarily crystalloid solutions developed pulmonary edema in association with normal left ventricular filling pressures but reduced colloid osmotic pressures. Treatment with furosemide was associated with a clearing of pulmonary edema and normalization of colloid osmotic pressure. The other 5 patients developing pulmonary edema received colloids and developed only elevated filling pressures. These observations emphasize that pulmonary edema may occur in the presence of a normal left ventricular filling pressure especially if large volume crystalloid infusion lowers colloid osmotic pressure. When large volumes of fluid are required it is safer to administer colloids which tend to maintain the colloid osmotic pressure. *(Stein L, Beraud JJ, Morissette M et al: Pulmonary edema during volume infusion. Cir 52:483-489, 1975)*

The Influence of Suction Catheter Tip Design on Tracheobronchial Trauma and Fluid Aspiration Efficiency

WILLIAM J. LINK, PhD*
EDMUND E. SPAETH, PhD†
WILLIAM M. WAHLE, MD‡
WILLIAM PENNY, MS§
JOHN L. GLOVER, MD‖

The suctioning efficiency and trauma-producing characteristics of five commercially available tracheobronchial suction catheters (Pharmaseal Tri-Flo, NCC Gentle-Flo, Argyle Aero-Flo, Argyle Dual Side-Hole, and Pharmaseal Whistle-Tip) were experimentally evaluated in anesthetized healthy dogs. The tendency of catheters to invaginate or "grab" tracheobronchial mucosa was observed with a bronchofiberscope during suctioning. Mucosal grabbing was seldom seen even at high (>300 torr) vacuum levels with the catheter tip in the trachea. All catheters were observed to invaginate mucosa in lobar and segmental bronchi, with the frequency of grabbing being a function of airway anatomy, airway size, catheter orientation, tip design, and vacuum level. Catheters with multiple side-holes appeared to invaginate mucosa less frequently than the single side-hole catheter.

Repeated suctioning of anesthetized healthy dogs followed by tracheobronchial excision, gross observation, and histologic examination of mucosal tissue biopsies demonstrated significant differences in the frequency and severity of lesions caused by the tracheobronchial suction procedure. All catheters were observed to damage airway lining, the damage related to multiple side-hole catheters appearing to be associated entirely with the act of catheter insertion and not with the application of vacuum. Only the Whistle-Tip design produced measurable damage beyond that related to catheter insertion.

The average tip-suctioning effectiveness for each catheter, determined *in vitro* by aspirating a thin, uniform layer of simulated mucus, was found to be significantly higher for the Tri-Flo and Whistle-Tip catheters than the others, the Aero-Flo being least effective. Preliminary attempts to demonstrate this difference in suctioning effectiveness by comparing the performance of the catheters which displayed the highest and lowest tip suction effectiveness in a standardized clinical suctioning procedure revealed no significant difference in the percentage of mucus removed by either catheter. Additional studies should clarify this apparent contradiction.

TRACHEOBRONCHIAL suction is a common and necessary procedure in patients whose ability to clear tracheobronchial secretions is impaired. In the past 2 decades, the procedures used in tracheobronchial aspiration have been given considerable attention, yielding several revisons in recommended technics. Aseptic technic to reduce bacteriologic colonization and cross-contamination in the trachea, moderate vacuum levels and limited duration of suctioning to reduce hypoxia, and the use of smooth, flexible catheters with vacuum control vents and side-holes near the tip to minimize trauma to tracheal and bronchial mucosa have been suggested.[1-3]

Paper received: 4/21/75

Accepted for publication: 8/11/75

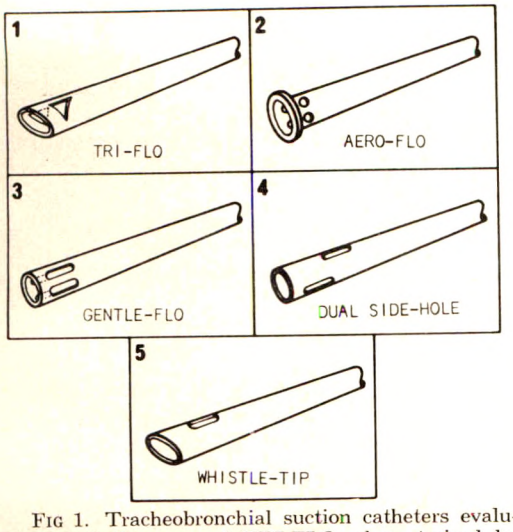

FIG 1. Tracheobronchial suction catheters evaluated: (1) Pharmaseal TRI-FLO, characterized by 2 triangular side-holes, offset from the center line and close to the beveled catheter tip. (2) Argyle AERO-FLO,characterized by 4 small, round side-holes near the expanded tip. (3) National Catheter Corporation GENTLE-FLO, characterized by 4 oval side-holes close to the tip. (4) Argyle Dual Side-Hole, characterized by 2 large side-holes somewhat removed from the tip. (5) Pharmaseal WHISTLE-TIP, characterized by a single side-hole.

Recently, Sackner and associates[4] reported no gross abnormalities in the distal trachea of dogs suctioned with the new Argyle Aero-Flo suction catheters (which supports an expanded tip and 4 small side-holes near the tip) while all dogs suctioned with conventional "whistle-tip" (single side-hole catheters) displayed gross changes, including edema, hyperemia, mucosal ulceration, and hemorrhage throughout the mucosa of the tracheobronchial tree. The Aero-Flo catheter has accordingly been referred to as "atraumatic."

Since this reported breakthrough in suction catheter tip design, two other suction catheters designed to reduce tracheobronchial trauma during aspiration have also become available. Unlike the conventional whistle-tip suction catheter with a single side-hole, the new low-trauma catheters have multiple side-holes of varying number and configuration. The multiple side-holes are significant in that the probability of occlusion of all the holes simultaneously during suctioning is decreased, reducing the opportunity for invaginating or "grabbing" the mucosa. However, by increasing the number of side-holes, there is also the possibility of reducing the suctioning effectiveness of the catheter as a result of excessive venting. Thus it bcomes important to determine not only the extent to which these new catheters reduce trauma, but also the extent to which their suctioning efficiency may be altered as a result.

In this study a variety of *in vitro* and *in vivo* animal experiments as well as preliminary clinical tests were used to investigate the tendency to induce tracheobronchial damage and the suctioning effectiveness of five types of catheters.

METHODS

Catheters evaluated included (fig 1): (1) Pharmaseal Tri-Flo, (2) National Catheter Corporation Gentle-Flo, (3) Argyle Aero-Flo, (4) Argyle Dual Side-Hole, and (5) Pharmaseal Whistle-Tip. The first three catheters are sold as either "atraumatic" or low-trauma catheters. The Pharmaseal Whistle-Tip was considered representative of the general class of single side-hole catheters. All catheters tested were size 14 French and were made of clear, flexible plastic material.

TRACHEOBRONCHIAL DAMAGE

Invagination of Mucosa.—The tendency of each catheter to invaginate tracheal and bronchial mucosa was observed visually by fiberoptic bronchoscopy in healthy mongrel dogs anesthetized with sodium pentobarbital (30 mg/kg) while varying the suctioning vacuum level (Gomco Aspirator, Model 930) over a range of 80 to 630 torr. This procedure was performed by two individuals, one regulating the vacuum level and the other noting the catheter performance while being unaware of the vacuum level. All five catheters were observed over the entire vacuum range in each of three animals, with a different observer for each animal.

Tracheobronchial Trauma. — To determine the extent of trauma accompanying extensive suctioning, a total of 42 healthy mongrel dogs weighing 11 to 18 kg were anesthetized with sodium pentobarbital, intubated, and maintained on spontaneous respiration. Following anesthesia and intubation, the mucosa of the tracheobronchial tree was observed with the bronchofiberscope.

Catheters were then fully inserted into the tracheobronchial tree, withdrawn slightly, and then 180 torr vacuum was applied for 3 to 5 seconds while steadily rotating

and withdrawing the catheter. The catheters, irrigated with water and lightly lubricated with mineral oil between each pass, were passed at 3-minute intervals over a 4-hour period, with a total of 80 passes in each animal. At the end of the procedure, the tracheobronchial tree was again observed with the bronchofiberscope, 35-mm color photographs being taken where lesions were present. The animals were then killed with an overdose of sodium pentobarbital, the thorax was opened, and the location of the tip of the endotracheal tube noted prior to excising the lungs. The airways were opened to the lobar bronchi, gross observations were made, and color photographs were taken. The tracheobronchial tree was then sectioned for histologic examination at a minimum of five locations: (1) 12.7 cm above the carina, (2) 7.6 cm above the carina, (3) 2.54 cm above the carina, (4) right mainstem bronchus, and (5) left mainstem bronchus. In addition, if specific gross lesions were noted, they were also sectioned for histologic examination. The microscopic slides were routinely prepared and the identity of the specimens was not revealed to the pathologist prior to examination.

The animals used in the trauma study fall into 8 groups, one group for each of the 5 catheters being tested and 3 control groups (table 1). To differentiate suction-related damage from damage due to merely inserting the catheters, catheters were passed in 4 dogs in the previously described manner except that no vacuum was applied. In addition, 2 animals served as "bronchofiberscope controls," in that they were handled as previously described while passing only the bronchofiberscope (no catheters), and 5 animals were "clean controls," in that they were anesthetized, intubated, and maintained under anesthesia for 4 hours without inserting catheters or bronchofiberscope into the tracheobronchial tree.

TABLE 1
Dogs Used in Tracheobronchial Damage Study Following Suctioning by Various Catheters

Group	Number of dogs	Catheter type	Number of catheter passes/animal	Bronchofiberscope, number of passes/animal	Vacuum applied
1	9	Tri-Flo	80	2	Yes
2	5	Aero-Flo	80	2	Yes
3	5	Gentle-Flo	80	2	Yes
4	4	Dual Side-Hole	80	2	Yes
5	8	Whistle-Tip	80	2	Yes
6	4	*	80	0	No
7	2	—	0	2	—
8	5	—	0	0	—

*One animal each—Tri-Flo, Aero-Flo, Dual Side-Hole and Whistle-Tip.

CATHETER SUCTION EFFICIENCY

This was evaluated by three approaches: (1) by aspirating viscous lubricating gel from the tracheobronchial tree in dogs (*in vivo* and *in vitro*), (2) by suctioning lubricating gel of varying viscosity and film thickness in a horizontal trough, and (3) in clinical trials.

Animal Studies.—Five dogs were anesthetized with sodium pentobarbital, intubated, maintained on spontaneous respiration, and the location of the carina with respect to the endotracheal tube established via bronchofiberoscopy. To simulate a film of mucus, a measured amount of lubricating gel (viscosity equal to 550 poise) was dispersed at given locations along the trachea by injecting it through a size 14 French catheter. Though various protocols were tried, a typical procedure was to inject a total of 3 ml of gel in boluses of ¼ ml at 1.27 cm intervals, starting 2.54 cm above the carina. A catheter was then passed to the level of the carina and uniformly withdrawn while applying vacuum (180 torr) for 5 seconds.

The amount of gel removed was weighed and the excess gel in the trachea was aspirated prior to the next catheter insertion. This procedure was repeated 10 times with each catheter. The animal was then killed, the lungs were removed from the thorax, and the dorsal surface of the trachea was longitudinally transected. The lungs were placed on a flat surface, with the trachea being slightly elevated (approximately 15° angle), lubricating gel was placed in the trachea, and the suctioning procedure was repeated as described above.

Catheter Tip Suction Efficiency.—Tracheobronchial secretions adhere to the wall of the tracheobronchial tree, forming a relatively thin film of variable thickness. Also, the inserted catheter lies with its axis essentially parallel to the airway wall. Hence, an

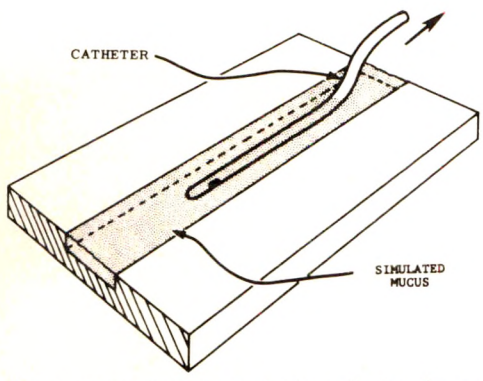

FIG 2. Tray used to evaluate catheter tip suction efficiency.

appropriate apparatus was designed for testing the suctioning efficiency of a catheter by positioning the catheter tip parallel to a simulated airway wall in contact with a thin film of mucus.

Troughs, either 2 or 3 mm deep, in flat trays (fig 2), were filled with lubricating gel of known viscosity (550 or 1200 poise) and suction was applied for 15 seconds, as the catheter tip was drawn through the film at a slow, uniform speed.

The Tri-Flo, Dual Side-Hole, and Whistle-Tip catheters were orientation sensitive. For example, the Whistle-Tip catheter suctioned essentially no gel when oriented such that the side eye did not contact the film, but aspirated a considerable amount of gel in the remaining orientations. Since during clinical suctioning the orientation of the side eye(s) of a catheter with respect to the airway wall is unknown and uncontrolled, it is necessary in determining the suction efficiency to average the amount of gel suctioned by an individual catheter over all possible orientations. Consequently, in the tray suctioning procedure, the orientation of the catheter tip was varied about a plane of symmetry in 45° increments from 0° (corresponding to "thumb-up" position of air vent) counterclockwise through 180°.

The amount of gel suctioned by the catheter in each 15-second trial was determined by weighing the catheter before and after the procedure. The catheter was cleaned between each trial and 10 trials were performed with each catheter in each orientation. For each given catheter, the numerical average of the amount of gel suctioned in all orientations has been termed the "orientation-averaged suction efficiency."

Clinical Tests.—An attempt was made to measure the suctioning efficiency of 2 catheters (Tri-Flo and Aero-Flo) in standardized suctioning procedures on patients in an intensive care unit. Four patients were suctioned in separate trials at ½-hour intervals over a 2 to 4-hour period. Two catheters were used at each suctioning procedure, with the first catheter being passed once in two of the trials and passed twice in the remaining 2 trials. The second catheter was passed additional times (usually twice) until the trachea was judged to be clear.

The first catheter used at each aspiration was alternated between the Tri-Flo and Aero-Flo, while the second catheter was not alternated. Hence, the tracheobronchial tree would be cleaned of mucus to approximately the same extent at each procedure. The mucus aspirated by each catheter was retained in an in-line mucus trap and, following each suctioning procedure, the catheters and the mucus traps were individually weighed. Consequently, the amount of mucus aspirated during single and double passes of the first catheter, as well as the remainder of the mucus removed by the second catheter, was determined for each tracheobronchial aspiration.

RESULTS AND DISCUSSION

Tracheobronchial Damage

Invagination of Mucosa.—Although it was difficult to determine with quantitative precision the transition point (in vacuum level) for each catheter between grabbing and not grabbing mucosa, several qualitative observations were made. The tendency for tissue invagination to occur was a strong function of catheter tip location and vacuum level, as well as tip design. Tissue grab always occurred, regardless of catheter type or vacuum level, when the catheter tip was "wedged" into a subsegmental bronchus of approximately the same diameter as the catheter itself, illustrating the value of withdrawing the catheter slightly before applying suction.

With the catheter tip located in lobar and segmental bronchi (with airway diameter less than 1.5 times larger than the catheter) tissue grab was observed with all catheters at both normal (100 to 300 torr) and high (>300 torr) vacuum levels. With the catheter tip in this location, the tendency to invaginate mucosa was intermittent and strongly dependent on bronchial anatomy and catheter orientation. The frequency of grabbing appeared to be lower with the multiple side-hole tip designs than with the

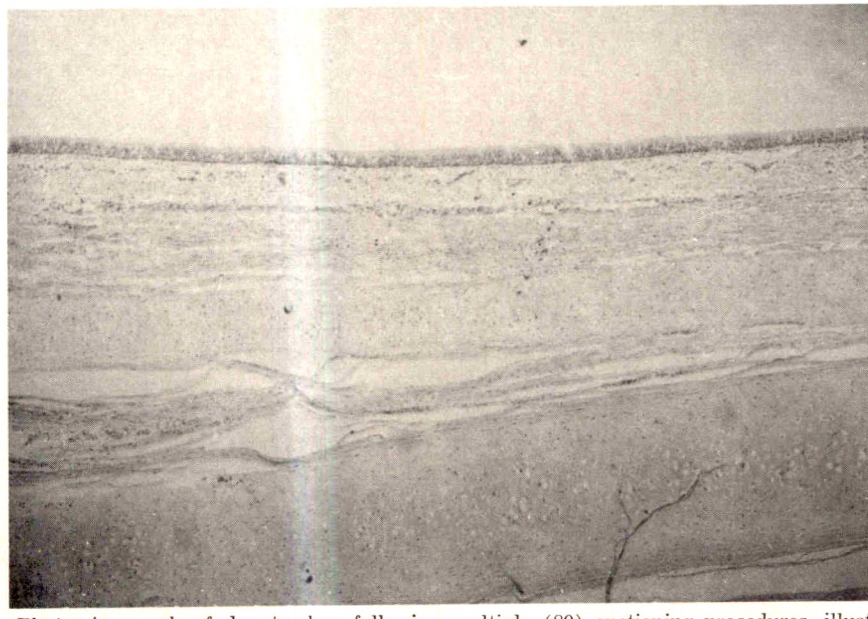

FIG 3. Photomicrograph of dog trachea following multiple (80) suctioning procedures, illustrating no loss of epithelium (H & E x 40).

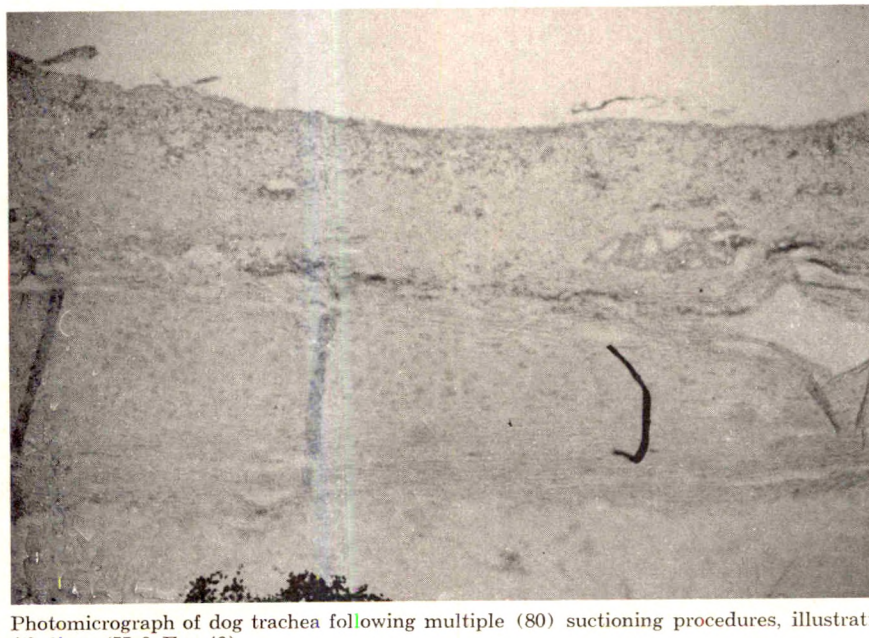

FIG 4. Photomicrograph of dog trachea following multiple (80) suctioning procedures, illustrating severe loss of epithelium (H & E x 40).

whistle-tip design, with this difference becoming more distinct as the vacuum level increased. No difference in the frequency of tissue grabbing could be distinguished between the various multiple side-hole tip designs, regardless of vacuum level. With the tip located in the trachea, mucosal grabbing was rarely observed even at high vacuum levels.

Tracheobronchial Trauma. — The results of the animal trauma studies indicate that all the catheters tested induce some degree of damage to the tracheobronchial tree. Gross observations of the airways following lung excision revealed mucosal linings which ranged in condition from being completely clear and clean to displaying multiple large, distinct hemorrhagic lesions (fig 3 and 4).

Furthermore, the degree of grossly observable damage to the tracheobronchial tree induced by any given catheter was quite variable, often spanning this entire range. Animals in which catheters were passed without applying vacuum (table 1, group 6) all displayed slight to moderate damage, with a limited number of distinct lesions. The airways in control animals, however, in which no catheters were passed (table 1, groups 7 and 8) grossly appeared quite normal, with no distinct lesions being observed.

All specimens were examined microscopically twice (on separate occasions) by a pathologist without knowing the identity of the slides. Observations recorded related to the degree of vascularity, extent of vascular dilation, epithelial loss, and presence of inflammation. Review of the histologic data revealed that the control animals in which no catheters were passed displayed various degrees of altered vascularity and inflammation similar to noncontrol animals. However, the existence of epithelial loss in the control animals in which no catheters were passed was markedly reduced compared to the noncontrol animals. Based on these observations, the presence or absence of epithelial loss was used as the histologic criterion for damage to the tracheobronchial mucosa from the suctioning procedure.

Damage Index.—To permit the direct comparison of the results of these various test groups, a numerical system of grading the degree of damage was established and a tracheobronchial *Damage Index* was defined, based on both gross and histologic observations:

0: Tracheobronchial mucosal lining was completely clear and clean under gross examination and displayed no microscopically observable loss of epithelium.

1: Minimal, questionable alterations were observed, either grossly or microscopically, which might be related to catheter suctioning.

2: Slight damage observed anywhere in the airway lining (gross and/or microscopic).

3: Moderate damage observed anywhere in the airway lining (gross and/or microscopic).

4: Severe damage observed anywhere in the airway lining (gross and/or microscopic).

Gross and microscopic observations previously tabulated were reviewed (without knowing to which animal the data corresponded) and a Damage Index was established for each animal. The range and average Damage Index for animals in each group are listed in table 2.

TABLE 2
Range and Average Tracheobronchial Damage Index in Experimental Animals Following Multiple Suctioning Procedures

Group	Catheter	Number of animals	Damage index	
			Range	Average
1	Tri-Flo	9	0-4	1.9
2	Aero-Flo	5	0-4	2.0
3	Gentle-Flo	5	1-3	2.2
4	Dual Side-Hole	4	1-3	2.0
5	Whistle-Tip	8	2-4	2.9
	Control animals			
6	Catheter*	4	2-3	2.25
7	Bronchoscope†	2	0-1	0.5
8	Clean‡	5	0-1	0.2

*One animal each with Tri-Flo, Aero-Flo, Dual Side-Hole and Whistle-Tip.
†Bronchofiberscope passed twice, no catheters passed.
‡Nothing passed into tracheobronchial tree.

The control group of dogs in which no catheters were passed (table 3, group 8) had an average Damage Index of 0.2. However, the average Damage Index of dogs suctioned with catheters containing multiple side-holes (table 1, groups 1 to 4) was significantly higher ($p<0.05$, single-tailed Student t test) ranging from 1.9 to 2.2. Considering the variability of the damage seen in the individual animals and the small number of animals in each group, the differences between the Damage Indexes of the various low-trauma catheter tip designs are not significant ($p>0.1$). On the other hand, the animals suctioned with the Whistle-Tip catheter (group 5) had an average Damage Index of 2.9, no animal having a value less than 2. This Damage Index is significantly higher than for the animals suctioned with multiple side-hole catheters ($p<0.1$).

Animals in group 6, in which catheters were passed without vacuum being applied, had an average Damage Index of 2.25. Hence, the physical act of inserting the catheter induces a measurable amount of trauma to the airway wall. Since the Damage Index of groups 1 to 4 is not significantly different from that of group 6, the damage related

TABLE 3

Amount of Aspirate Removed by Aero-Flo and Tri-Flo Catheters, as Well as Percentage of Total Aspirate Removed, in Single-Pass and Double-Pass Clinical Trials in 4 Patients

Patient	Number of samples	First catheter			Second catheter*		Portion of total aspirate removed by first catheter (average), %
		Type	Number of passes	Average aspirate, gm	Type	Average aspirate, gm	
1	3	Tri-Flo	1	1.47	Tri-Flo	3.9	28
	2	Aero-Flo	1	2.0	Tri-Flo	5.15	28
2	2	Tri-Flo	1	1.2	Tri-Flo	2.6	32
	3	Aero-Flo	1	1.9	Tri-Flo	3.5	36
3	5	Tri-Flo	2	0.67	Tri-Flo	0.33	69
	5	Aero-Flo	2	0.75	Tri-Flo	0.37	71
4	5	Tri-Flo	2	0.81	Tri-Flo	0.43	76
	5	Aero-Flo	2	0.90	Tri-Flo	0.448	69

*Second catheter was usually passed twice or until trachea was judged to be clear of mucus.

to suctioning with multiple side-holed catheters appears attributable to physically inserting the catheters and not to suctioning or mucosal grabbing. On the other hand, with the Whistle-Tip catheter, additional damage beyond that related to the insertion of the catheter seems apparent.

CATHETER SUCTION EFFICIENCY

Animal Studies.—The studies in which a given amount of simulated mucus (lubricating gel of viscosity equal to 550 poise) was injected at known locations in the trachea of dogs were unrevealing. Extreme variability in the data, even between repetitive experiments within the same animal, led to large uncertainties and low reproducibility. This was presumably due to lack of control over the location of the mucus sample and the probability of contact of the catheter tip with the mucus.

Catheter-Tip Suction Efficiency.—Since it is obviously the tip of the catheter that aspirates mucus in a suctioning procedure, the suction efficiency of the catheter tip should be indicative of its clinical suctioning effectiveness. By aspirating simulated mucus in uniform thin films in a flat trough, the randomness in the contact between the catheter tip and mucus is diminished greatly as compared to the animal studies described above. Lubricating gels of viscosities equal to 550 and 1200 poise were aspirated in thin films of 2 and 3 mm depth. (It should be noted here that, though the viscosity of the simulated mucus fell in the physiologic range,[5] the viscoelastic and non-Newtonian nature of mucus was not closely simulated.)

A significant difference in the orientation-averaged tip suctioning efficiency was exhibited between the various catheters (fig 5 and 6). For example, in a 3 mm film of lubricating gel with a viscosity of 550 poise, the suctioning efficiency of the Tri-Flo and Whistle-Tip catheters was approximately 4 times greater than the suctioning efficiency of the Aero-Flo catheter ($p<0.01$). The trend displayed by these data remained consistent as the film thickness and lubricating gel viscosity were varied.

To further simulate actual conditions during tracheobronchial suctioning, additional

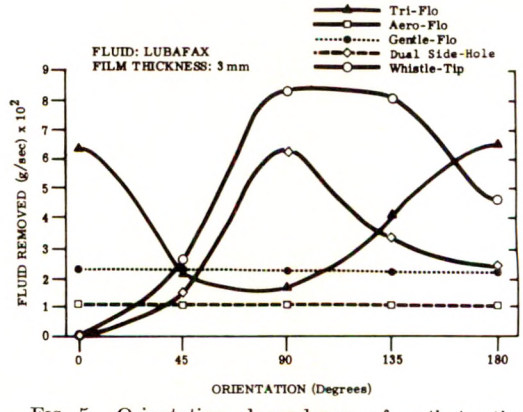

FIG 5. Orientation dependency of catheter-tip suction effectiveness in 3 mm film of lubricating mucus (viscosity = 550 poise).

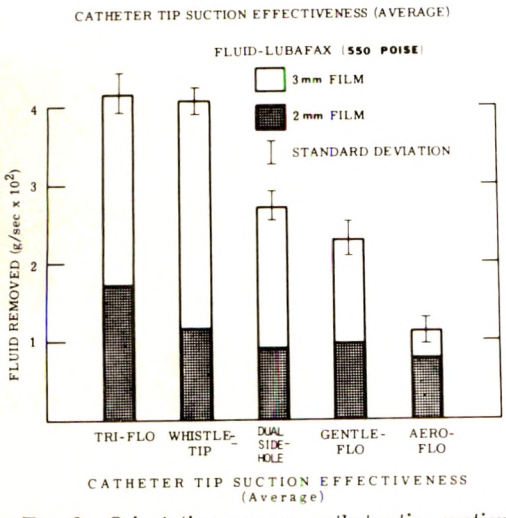

FIG 6. Orientation-average catheter-tip suction effectiveness evaluated in 2 and 3 mm films of lubricating gel (viscosity = 550 poise).

experiments were conducted with the trough inside a 2.5-cm diameter cylindrical chamber evacuated during suctioning to a pressure of -2.5 cm H_2O (corresponding to tracheal pressures measured *in vivo* during suctioning). This experiment, simulating tracheal air-flow conditions, showed no significant changes in relative uptake rates.

Clinical Trials.—In an attempt to demonstrate the influence of this measured variation in catheter-tip suction efficiency in a clinical suctioning procedure, preliminary clinical experiments were conducted in which patients were suctioned with a combination of the Tri-Flo and Aero-Flo catheters, as described previously. These two catheters were selected since they represent the highest and lowest catheter-tip suction efficiency. Each suction procedure consisted of a single or double passage of either the Tri-Flo or the Aero-Flo catheter, followed by additional passes with the Tri-Flo catheter until the tracheobronchial tree was judged to be clean. Approximately one-third of the mucus was removed during the first pass and a second third was removed during the second pass, indicating a need for multiple-pass suctioning procedures to obtain effective cleaning (table 3). No significant difference was observed in the percentage of mucus removed by either catheter in these preliminary experiments. Due to the limited number of trials and the difficulty encountered in obtaining precise data during these tests, no overall conclusions have been drawn from these data.

AGE AND METHOXYFLURANE NEPHROTOXICITY The influence of age on development of mechoxyflurane (MOF) nephrotoxicity was determined in Fischer 344 rats. Serum ionic fluoride after 2 hours exposure to 0.5% MOF was least in young rats (6 weeks) and highest in the 12 month old animals. Polyuria occurred only in animals more than 6 weeks old. This relative protection against MOF nephrotoxicity in young rats is probably related to less drug storage and thus less metabolite formation plus greater fluoride bone storage in these young animals. *(Bell LE, Hitt BA, Mazze RI: The influence of age on the distribution, metabolism and excretion of methoxyflurane in Fischer 344 rats: A possible relationship to nephrotoxicity. Case History Number 89:
A Life-Threatening Complication of Cricothyroid Membrane Puncture

Y. K. POON, MB, BS, FFARCS*

THIS report describes an episode of acute upper-airway obstruction secondary to extensive subcutaneous emphysema in a patient in whom a catheter was inserted through the cricothyroid membrane to aid tracheal intubation.

A 20-year-old, 142 cm, 37.2 kg man with long-standing severe rheumatoid arthritis was admitted for left total hip replacement, following a similar procedure on the right a month earlier. In addition to his short stature and multiple large joint deformities, relevant physical findings included cervical spine rigidity and limitation of movement without deformity, a small receding mandible, and large prominent upper central teeth. There was no evidence of temporomandibular or cricoarytenoid joint abnormality.

At the time of the first procedure, nasotracheal intubation was moderately difficult during N_2O-O_2-halothane anesthesia with spontaneous respiration. It was impossible to visualize the larynx, but a 6-mm tracheal tube was inserted blindly. The remainder of the anesthetic procedure was uneventful. A fiberoptic laryngoscope was not available at the time of this or the later operation.

For the second procedure, anesthesia was induced in a similar fashion, but blind nasotracheal intubation was unsuccessful after several attempts. It was then elected to thread a small catheter up through the larynx as a guide for the endotracheal tube. The cricothyroid membrane was punctured with a 17-gauge needle-over-catheter IV unit and the catheter was threaded up into the mouth. As a 7-mm orotracheal tube passed over the catheter would not enter the trachea, the catheter was directed up through the nose and a 6-mm nasotracheal tube passed over the catheter into the trachea. The catheter was removed, the tracheal tube cuff inflated, and anesthesia and operation proceeded uneventfully. Respiration was spontaneous during N_2O-O_2-halothane anesthesia. There was no evidence of subcutaneous emphysema at the termination of the surgical procedure.

The patient was extubated in the recovery room following return of consciousness. The initial postoperative course was uneventful, and the patient was transferred to his ward 90 minutes after operation. At that time, a small amount of subcutaneous air was noted in the anterior neck.

On the ward, narcotic analgesics were administered when the patient was noted to be grunting and complaining of pain at the operative site. He also complained of nasal congestion and blew his nose repeatedly. Four hours postoperatively, the subcutaneous emphysema had increased dramatically and involved the face, neck, and upper thorax, but the patient was not in respiratory distress. Forty minutes later, the subcutaneous emphysema had further progressed, with involvement of the lower trunk and increased swelling of the neck and face. The patient was now cyanotic and in obvious

FIGURE. Supine chest (portable) radiograph, 5 hours postoperation, demonstrates extensive subcutaneous emphysema, pneumomediastinum, and right pneumothorax.

respiratory distress, with marked inspiratory stridor. A chest radiograph was taken at this time (figure).

Because of this acute deterioration, and in view of the earlier difficulties with tracheal intubation, the patient was immediately returned to the operating room for chest-tube insertion and tracheostomy. O_2 (100%) was administered by face mask and local anesthetic was infiltrated in the neck. With the skin incision, air was released from the neck with a hissing sound, immediately improving the inspiratory stridor. Exposure of the anterior trachea revealed a small puncture.

The dramatic improvement in the patient's condition made it unnecessary to proceed with the tracheostomy. A subcutaneous drain was inserted in the neck incision and was connected to suction. Arterial blood gases sampled immediately after this procedure and throughout the subsequent recovery period were normal. The right chest tube was removed after 3 days. A small left pneumothorax developed but did not require drainage. The lungs were fully expanded by the 12th postoperative day and all subcutaneous emphysema had resolved by the 18th day. The patient was discharged from hospital with no sequelae from this complication.

Discussion

Puncture of the cricothyroid membrane allows rapid and relatively easy access to the lumen of the trachea, bypassing the

Comment

DOUGLAS B. CRAIG, MD, FRCP(C)

Enthusiasm for the use of technics requiring cricothyroid membrane puncture has not been accompanied by similarly increased awareness of the potential complications inherent in the procedure. This case report should serve as a dramatic reminder that major complications do occur. Air extravasation into subcutaneous tissues and the mediastinum has been the most common major complication previously reported. In this patient, the extent of the tissue emphysema, and the severity of its effects, producing airway obstruction, likely resulted from 2 factors: the generalized tissue abnormality associated with chronic severe rheumatoid arthritis, and the increased tracheal pressure due to nose blowing, promoting leakage and spread of air.

Cricothyroid membrane puncture as an aid to intubation should now rarely be required, due to the availability of reliable fiberoptic laryngoscopes. For many other situations, however, cricothyroid puncture remains part of valuable, and at times life-saving, technics. Like any other procedure, its safe use requires knowledge of its indications and contraindications, as well as the early recognition and management of complications.

mouth, pharynx, and larynx. Use of this technic has increased, associated with the introduction of venturi devices for mechanical ventilation during laryngoscopy[1] and laryngectomy.[2] The percutaneous transtracheal ventilation technic has been the subject of a recent review.[3] Other procedures utilizing cricothyroid membrane puncture have included tracheal lavage and sputum sampling,[4] local anesthetic spraying of the trachea,[5] bronchography,[6] emergency ventilation,[7] and guiding of endotracheal tubes over catheters inserted upward into the pharynx.[8]

Although the tissues pierced are thin, it is possible for air, blood, bacteria, contrast media, and needle debris to enter the soft tissues of the neck, where they may produce serious complications. As illustrated by this case report, any postpuncture increase in tracheal pressure, such as that produced by exhalation against a closed glottis as in grunting or coughing, or by high-pressure gas insufflation, increases the risk of air leakage into subcutaneous tissue. Larger-bore needles and catheters increase the likelihood of air leakage. It has been suggested that the incidence and severity of tissue emphysema can be minimized by inserting the needle through the skin at some distance from the tracheal perforation site and by application of pressure to the anterior neck after removal of the catheter.[9]

Subcutaneous emphysema localized to the neck occurred in 5/102 patients and 2/13 volunteers reported by Kalinske and associates.[4] Two in each group developed mediastinal emphysema. A case of severe, life-threatening mediastinal emphysema, reported by Massey,[10] resembles the course of events in our patient. In both cases, air leakage appears to have been the result of high intratracheal pressures produced by the patient in the postpuncture period. The nose-blowing by our patient would likely produce intratracheal pressures considerably higher than would grunting, and therefore explains the severity of his course. Another contributing factor was likely a generalized tissue abnormality associated with his chronic illness and debility.

Respiratory infections increase the hazard of mediastinal infection, and bleeding diatheses increase the risk of hematoma formation. Hemoptysis following cricothyroid membrane puncture is frequent, moderate, and usually transient.[4] One case of hypoxic death thought to be due to blood obstructing the trachea has been reported.[11] Wound infections are now rare. Two patients with tuberculous granulomas of the needle tract in the neck were reported by Pecora.[12] Breakage of needles has occurred when patients have suddenly coughed with the needle in place.[13] Bradycardia, cardiac arrest, and arrhythmias have occurred in unpremedicated patients and where tracheal suction produced hypoxemia in critically ill patients.[11] Vomiting and aspiration have been reported, as well as one incident of respiratory arrest, likely caused by pain and vagal stimulation.[11]

The most common minor complaints are neck pain or sore throat, occurring in 50% of patients following transtracheal bronchography.[6] Transient hoarseness and dysphonia are also common.

This report serves as a reminder that serious complications following cricothyroid membrane puncture can and do occur. Their incidence and severity should be minimized if the following guidelines are followed:

1. Awareness of the potential complications due to air extravasation associated with increased airway pressure. This may occur during ventilation using positive pressure or when airway pressure increases with grunting, coughing, sneezing, or nose-blowing.

2. Avoiding the procedure in patients with bleeding diatheses and those with severe cough. Severe connective tissue diseases should be considered a relative contraindication.

3. Applying pressure to the puncture wound for several minutes and keeping the patient flat in bed for several hours.

4. Using the smallest-bore needle and catheter possible.

5. Administering supplemental O_2 if the patient is already hypoxemic or if suctioning is to be performed.

6. Recognizing complications early and treating them appropriately.

PEEP, PCWP and CARDIAC OUTPUT The authors investigated the effect of PEEP upon the pulmonary circulation in 12 patients requiring postoperative mechanical ventilation. Cardiac index did not change with 5 or 10 cm H_2O PEEP but decreased at levels above 10 cm H_2O. The fall in cardiac output was frequently accompanied by a marked increase in PCWP. The authors speculate that high intra-aveolar pressures created by PEEP restrict flow through the pulmonary circulation and decrease cardiac output. Furthermore, in this situation, a balloon-tipped catheter no longer reflects left atrial pressure but rather the higher alveolar pressure which has occluded the pulmonary capillaries. It would be incorrect to consider the increase in PCWP as evidence of volume overload or left ventricular failure. During PEEP, a high PCWP may reflect high resistance to flow in the pulmonary circulation and a need to reduce the level of PEEP to permit maintenance of an adequate cardiac output. *(Hobelman CF, Smith DE, Virgilio RW et al: Hemodynamic alterations with positive end-expiratory pressure: The contribution of the pulmonary vasculature. An Unusual Problem in Nasotracheal Extubation

GARRY S. SKLAR, MD*
ANTONIO E. ALFONSO, MD†
BENTON D. KING, MD‡
Brooklyn, New York§

NASOTRACHEAL intubation is widely used for prolonged intubation and for certain operations around the mouth. We wish to report an unusual problem in extubation and to recommend precautionary measures.

REPORT OF A CASE

A 69-year-old man underwent partial glossectomy with N_2O-O_2-droperidol-fentanyl anesthesia with an 8.5 mm nasotracheal tube. The cuff and inflation tube were added to the endotracheal tube and a plastic adapter was added to the syringe end of the inflation tube. The inflation tube was not fused to the main tube.

After an uneventful anesthetic procedure and recovery, as the nasotracheal tube was withdrawn from the trachea, larynx, pharynx, and nose, the inflation tube and adapter were pulled, as if around a pulley, into the patient's nose (fig 1). The entire endotracheal tube was out of the patient's nose, but traction on the inflation tube was un-

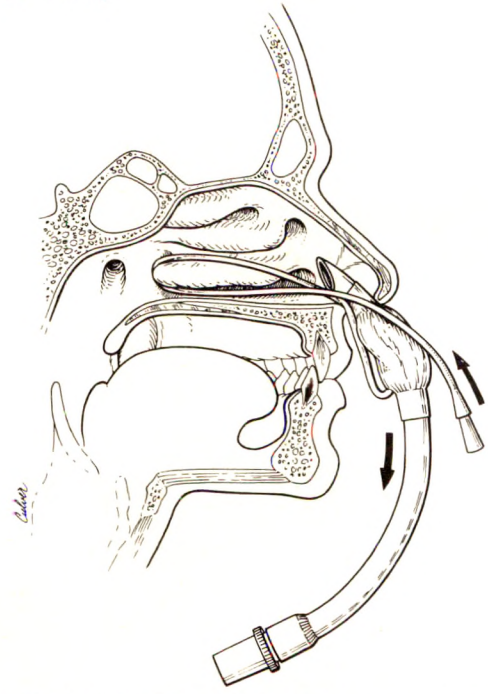

FIG 1. Inflation tube being drawn into nostril by "pulley" action of turbinate.

FIG 2. How plastic adapter probably caused inflation tube to be trapped in nostril.

successful in dislodging the trapped end, because of the plastic adapter (fig 2).

The problem was solved by cutting the inflation tube, sewing the end of it to a nasogastric tube, passing the nasogastric tube into the same nostril, and retrieving it through the mouth with the attached inflation tube and plastic adapter following.

COMMENT

The inflation tube had undoubtedly become wrapped around a nasal turbinate. Forceful pulling could only result in unnecessary trauma and would only wedge the plastic adapter against the turbinate. The nasogastric tube allowed the adapter to change direction and thus be removed through the mouth.

In retrospect, as the inflation tube was pulled into the nostril during extraction of the endotracheal tube, the plastic adapter should have been removed; this probably would have allowed the inflation tube to be removed without difficulty. Had the plastic adapter come off in the nose, the potential danger of infection or aspiration would arise.

This incident suggests the desirability of using endotracheal tubes with integral cuffs and fused inflation tubes, or inflation tubes with a soft tapered rubber end for inflation, for nasotracheal intubation. It should also be noted that the fused joint of inflation tubes on reusable endotracheal tubes with integral cuffs may become separated with repeated use and sterilization. Thus, frequently used tubes should be employed with caution.

A recent review[1] of complications of tracheal intubation did not mention this problem, nor is it mentioned in standard anesthesia texts. Awareness of this unusual occurrence and its management should help prevent future mishaps of this nature.

A Simple Method of Inserting a Nasogastric Tube for Anesthesia

ANIS BARAKA, MD*

MANY different technics for the insertion of a nasogastric tube have been recommended.[1-10] A simple technic, originally proposed by Conroy,[2] is to introduce the nasogastric tube via an endotracheal tube inserted through the nose into the esophagus.

An alternative method is to introduce the nasogastric tube via a rectal tube, which also can be inserted blindly through the nose into the esophagus and even into the stomach. The firm but flexible wall of the rectal tube, its adequate length, and its smooth terminal outlet make it more suitable than an endotracheal tube for blind nasoesophageal intubation (figure).

*Chairman, Department of Anesthesiology, American University of Beirut, Beirut, Lebanon.

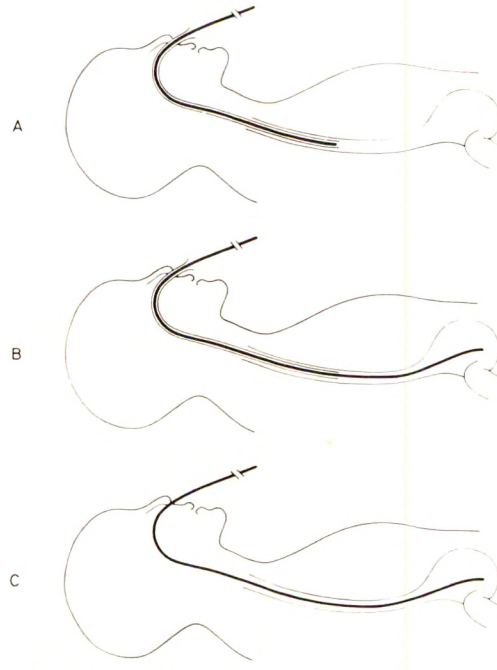

FIGURE. Technic of inserting nasogastric and rectal tubes: A. Rectal tube, enclosing nasogastric tube, is inserted blindly from nose into esophagus. B. Nasogastric tube is then threaded further through rectal tube into stomach. C. Rectal tube is withdrawn while nasogastric tube is left in place.

Acute Cardiovascular Collapse After Intravenous Phytonadione

PAUL BARASH, MD*
LUKE M. KITAHATA, MD, PhD†
SAMUEL MANDEL, MD‡
New Haven, Connecticut§

ALTHOUGH a clinical impression[1,2] exists that phytonadione (AquaMephyton®) given IV can in rare cases cause hypotension, review of the literature reveals no documentation of this impression. The following case report suggests that phytonadione given IV may, however, be associated with cardiovascular collapse.

REPORT OF A CASE

A 43-year-old man with squamous cell carcinoma of the vocal cord entered Yale-New Haven Hospital for a total laryngectomy. He had been admitted 10 months before for evaluation and treatment of Laennec's cirrhosis. During the prior admission, carcinoma of the left vocal cord was also

Paper received: 6/27/75
Accepted for publication: 7/15/75

diagnosed, for which the patient received radiotherapy. A liver biopsy at that time revealed severe nutritional cirrhosis and alcoholic hepatitis. The patient gave a history of heavy alcoholic ingestion over a number of years; he was also a heavy cigarette smoker (3 packs/day). His only previous operation was uneventful removal of a "cyst on the spine" 20 years previously.

At the time of the present admission, the patient had hoarseness and occasional bilirubinuria, but otherwise was free of symptoms. His weight was 64 kg, and his vital signs were normal. Pertinent positive physical findings revealed the stigmata of liver disease: palmar erythema, gynecomastia, hepatosplenomegaly, and ascites.

Laboratory data showed hemoglobin of 10.8% and a platelet count of 160,000/ml. Urinalysis was negative. Prothrombin time was 14.2 sec (control 10.8 sec) and partial thromboplastin time 43 sec (control 31.5 sec). Serum electrolytes (mEq/L) were Na^+ 134, Cl^- 85, K^+ 3.1, and HCO_3 38. Total protein was 7 gm % (albumin 2.5 gm % and globulin 4.5 gm %). Liver profile showed total serum bilirubin to be 2.22 mg % (direct 1.86%), SGOT 60 μ (normal <35 μ), ammonia 176 mg %, cephalin flocculation 4+, and thymol turbidity 8.4 μ (normal <5 μ); serum amylase, lipase, LDH, and alkaline phosphatase were all normal. Chest x-ray revealed a left pleural effusion. ECG showed sinus tachycardia and T-wave abnormality "suggestive of electrolyte abnormality or drug effect."

At 0630 hr, the patient was premedicated with diazepam (10 mg) and scopolamine (0.5 mg) IM. Prior to induction at 0830, an intra-arterial line and a thermodilution Swan-Ganz catheter[3] were placed. Induction of anesthesia was with 20 mg of IV diazepam. Orotracheal intubation was facilitated with 10 mg of IV pancuronium. Anesthesia was then maintained with O_2-halothane (99:1). A tracheostomy was performed and the airway was then secured with a right-angle spiral-wire endotracheal tube (Boyan) through the tracheal stoma. Operation proceeded uneventfully.

Vital signs remained stable throughout the next 5 hours of operation, with blood pressure 150/90 torr, pulmonary artery pressure (PAP) 25/14 torr (table), pulse rate 100, and adequate hourly urine output. Albumin, whole blood, and lactated Ringer's solution were used for volume replacement.

At 1300 hr, halothane was discontinued and the patient received O_2 while the dressing was applied. At 1315, since there was still persistent oozing from the cutaneous suture line, 10 mg of phytonadione was injected IV over 10 minutes. Five minutes later, there was a precipitous drop in BP to 30/10 torr and a drop in PAP to 10/5 torr. The ECG showed a sinus rhythm at a rate of 80/minute. The patient immediately was placed in Trendelenburg position and $CaCl_2$ (1 gm), mephentermine (30 mg), dexamethasone (8 mg) were given IV. In addition, lactated Ringer's solution, whole blood, and fresh frozen plasma were administered. Within 3 minutes, the BP rose to 80/50 torr and returned to the prehypotensive level within 10 minutes.

Upon arrival in the recovery room, the patient was responsive to his name and could move all extremities. However, 45 minutes later, increased bleeding necessitated reexploration of the surgical incision, under general anesthesia, which revealed several bleeding points. These were suture ligated.

At 1900 hr, because of prolonged prothrombin time, an additional dose of 25 mg of phytonadione was administered IM, without incident. On the 2nd postoperative day, 10 mg of phytonadione was administered IV in 100 ml of D/5-0.2 N saline solution over 1 hour, without untoward effect. The remainder of his hospital course was uneventful.

DISCUSSION

Phytonadione is the aqueous colloidal solution of vitamin K_1. Parenteral administration is indicated where the oral route is contraindicated or in emergency situations. According to Udall,[4] phytonadione should be administered IV in emergency situations where a severe coagulation defect is present secondary to a decreased amount of vitamin K_1. Absorption from an IM injection in this situation can be erratic and should not be relied upon. However, because the action of vitamin K_1 is detectable only 3 hours after IV administration, fresh frozen plasma should be given during this latent period, if bleeding secondary to hypoprothrombinemia is severe.

The etiology of the hypotension in the present case is conjectural. With the acute decrease in PAP, it would appear that the hypotension was caused by peripheral vasodilation and accompanied by a fall in PAP

TABLE
Significant Cardiorespiratory Measurements

Time	BP, torr	PAP, torr	pH	$Paco_2$, torr	Pao_2, torr	$P\bar{v}o_2$	BE/ mEq/L	Fio_2	Hct	Cardiac output, L/min

1345 hr	150/90	25/9	7.59	23	110		+5	1.0	36	5.70
1410 hr	150/90	25/9	7.54	30	351		+4	1.0	37	

rather than a rise, which would have been expected if myocardial depression were a major cause. This acute decrease in PAP suggests that left ventricular failure was not present, but it does not necessarily rule out the presence of right ventricular failure. However, the latter is unlikely, since the cardiac output of 5.7 L/min was obtained only 15 minutes later (table). Therefore, a primary myocardial etiology of the hypotension is unlikely, so it appears that peripheral vasodilation was primarily responsible.

The patient was stable, no medications were administered, and no surgical manipulation was performed during this period. Further, the anesthetic procedure had been terminated 25 minutes before the onset of hypotension. Therefore, it is highly unlikely that there was a temporal relationship to any event other than the administration of vitamin K_1.

An allergic or anaphylactic response is doubtful, since the patient had subsequent injections (an IM injection 6 hours postoperatively and a prolonged IV injection over a 1-hour period on the 2nd postoperative day) without untoward effects. Thus, it appears that either the emulsion (polyethylated fatty-acid derivatives and dextrose) or the active drug has a peripheral vasodilating effect.[5]

The present case is the first documented report of a vascular reaction to IV phytonadione, although fatal reactions have been reported with other types of fat emulsions.[2] There have been no reports of fatalities associated with parenteral use of water-soluble vitamin K analogues, but these are ineffective in treating drug-induced hypoprothrombinemia.[2] The fact that the hypotension followed IV administration of phytonadione could be explained on the basis of higher blood levels associated with IV injection.

The placement of a Swan-Ganz catheter in this case was fortuitous in documenting the precipitous drop in PAP associated with a drop in systemic arterial pressure following IV injection of phytonadione.

This case suggests that therapy for hypotension following injection of phytonadione should be directed at correcting the acute peripheral vasodilation.

A Guide for Authors

Anesthesia and Analgesia . . . Current Researches invites original manuscripts on subjects pertinent to the specialty of anesthesiology. Original articles accepted for publication, or papers presented at the Society's annual scientific meetings which subsequently may be published in the Journal, become the property of the International Anesthesia Research Society. Reproduction in whole or in part is not permitted except by written consent of the publisher and the author.

Submit manuscripts in triplicate to—
T. H. Seldon, M.D., Editor
Kahler East, Suite C
Rochester, Minnesota 55901, U.S.A.

All papers are reviewed by the Editorial Board and other selected referees. If accepted for publication, editorial revisions may be made to aid clarity and understanding without altering the meaning. Edited copy is submitted to authors for approval before it is sent to the printer. Page proof will be submitted to authors for final approval. Reprint order forms will accompany page proof.

Titles should be concise but informative, with thought given to the use of key words for indexing. Ninety characters, including punctuation and spaces, should be sufficient.

Coauthors' names should be followed by the major degree, professional affiliation, and address.

Abstract: On the first page of manuscript, an abstract of from 50 to 250 words, according to length of article, but not exceeding one double-spaced typed page, should describe purpose, methods, results, and conclusions, as succinctly as possible. This replaces both former Capsule Review and Summary, but is the same in content and format.

Type manuscript (in triplicate) on 8½ x 11-inch white paper, with 1½ inch margins at top, bottom, and both sides. Double space ALL typing, including references, legends and footnotes.

References: About 20 references are acceptable. In extensive reviews of the literature, readers will be advised that longer reference citations can be obtained from author. Citations should include (1) last name of author followed by initials without internal punctuation; (2) commas separate names and initials of authors; (3) four or more authors are designated as "et al;" (4) journal name is abbreviated according to Index Medicus style; (5) references from books show (a) city of publication, name of publisher, date of publication, after book title; (6) journal references give volume, first and last page numbers, year. (See previous issues of *Anesth & Analg* for style.)

Tables should be self-explanatory and should supplement, not duplicate, the text.

Photographs should have sharp contrast, be on *glossy* paper unmounted, and 4 by 5 inches or larger. *Polaroid prints damage easily in handling and thus may reproduce indistinctly. Glossy prints are preferred.* Submit photographs of roentgenograms with contrasts as in original and sharply defined; "TOP" must be identified. All illustrative materials, charts, etc., must be submitted in triplicate, clearly numbered according to text and legend.

Lettering on charts and graphs must be large enough to be legible when reduced in size. Curves, scatter dots, etc., should contrast with reference lines.

Drawings must be in black (India) ink on white background and should be of professional quality.

Legends for illustrations should be concise and typed on one page. Legends for photomicrographs should show stain and magnification data.

Drug names used in the text should be generic unless trade names are essential to the discussion.

Multiple Publication: To avoid violating existing copyrights, a statement should accompany each submitted article indicating that the material in question:

1. Has not been simultaneously submitted to another journal.
2. Has not been previously published elsewhere.

a. Abstracts of 400 words or less do not constitute prior publication.

b. A report issued by requirement of a governmental agency or comparable granting institution does not constitute prior publication.

c. Extracting by news media does not constitute prior publication unless all vital tables and pertinent conclusions are involved or unless such publication was actively solicited by the authors.

Legal considerations require letters of permission from authors and publishers for use of illustrations or quotations originally appearing elsewhere, and also written permission for use of photographs of identifiable patients. Identifying information, such as names, initials, hospital numbers, and dates, must be avoided.

When experimentation involving human subjects is reported, an appropriate statement regarding informed consent should be made.

Case reports should include only significant data. Laboratory findings should be restricted to those pertinent to the discussion.

Symbols used for respiratory physiology should follow Fed. Proc. 9:602, 1950.

Explanation of abbreviations and symbols used within the text should be added as a footnote.

Example: torr: Unit of pressure of 1 mm. of mercury at 0° C. and standard gravity.

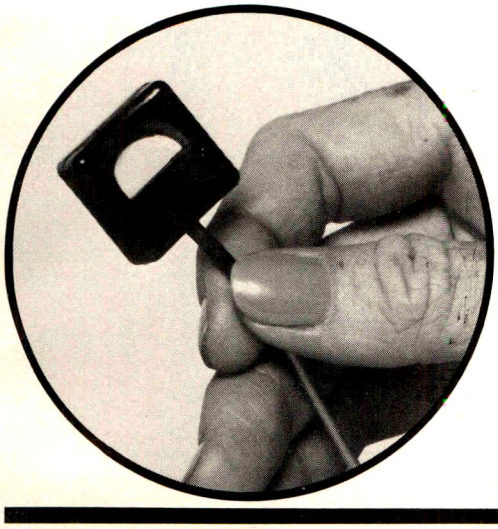
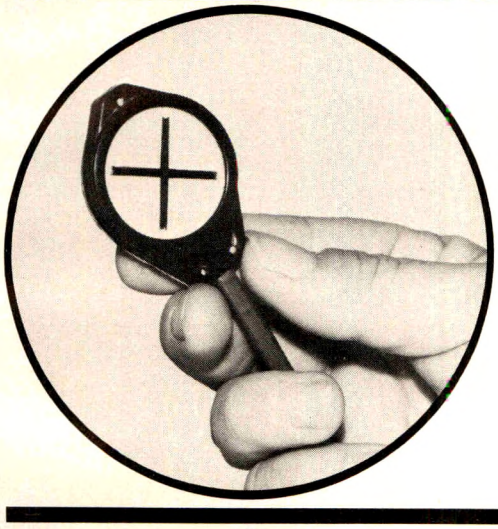
VERSATONE® MULTI-PURPOSE DOPPLER INSTRUMENT



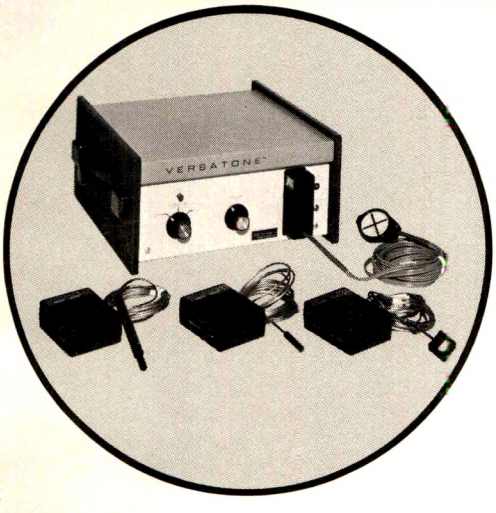
FOR MONITORING DOPPLER SOUNDS OF BLOOD FLOW AND TO TAKE DOPPLER SYSTOLIC BLOOD PRESSURE

This sensitive Doppler probe is easy to tape in position for non-invasive detection and monitoring of arterial blood flow during surgery. Used with an occlusive cuff and manometer, systolic blood pressures may be obtained even on infants and hypotensive patients.



FOR EARLY DETECTION OF VENOUS AIR EMBOLISM

This sensitive wide-angle Doppler probe is particularly well suited for the detection of venous air emboli which may occur during neurosurgical procedures performed with the patient in the upright position. It also detects motion of the heart muscle, heart valves and blood flow.



VERSATONE D8 DOPPLER

The Model D8 VERSATONE Doppler instrument is designed to use interchangeable probes of various frequencies and configurations. It is powered by a rechargeable battery and has a built-in loudspeaker. Options include an electrocautery sensor and cut-out, a molded earset for private listening, and a chart recording circuit. The two probes shown above are particularly useful to the anesthesiologist. Two sizes of pencil shaped probes are also available. These are useful for intraoperative assessment of flow in exposed vessels, as well as for transcutaneous flow detection.

In 16 years of use in the United States, FLUOTHANE (halothane) has been administered over 100 million times in a wide variety of surgical procedures. 100 million ...extensive usage and evaluation that attests to FLUOTHANE as the most widely used inhalant anesthetic.

Since it was first introduced, over 4,000 papers worldwide have been published, ranging from review articles to in-depth studies. 4,000 papers... a bibliographic record of note on the most widely used inhalant anesthetic.

In a continuing program of informational services on anesthesiology, Ayerst provides printed and audiovisual aids reflecting the opinions and experiences of recognized authorities in the field. These include the highly regarded series on *Anesthesia Rounds* and *Clinical Aspects of Anesthesiology*, as well as several films of educational value—all available through your Ayerst Representative.

FLUOTHANE® (HALOTHANE) ...OVER 100 MILLION ADMINISTRATIONS

- nonflammable, nonexplosive
- permits use of high concentrations of oxygen
- allows free use of cautery for more adequate control of bleeding
- minimal odor facilitates smooth, rapid induction, reduces patient distress
- early obtundation of pharyngeal and laryngeal reflexes facilitates intubation
- lessens airway problems
- permits rapid adjustment of depth of anesthesia
- emergence is rapid and tranquil with quick recovery of protective reflexes
- minimal nausea and vomiting, shorter recovery room stay

Ayerst®

FLUOTHANE®

brand of halothane

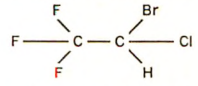
the most widely used inhalant anesthetic

from **Ayerst**

for precision, experience, quality, and service

(Complete text of package circular.)

Description. FLUOTHANE, brand of halothane, is an inhalation anesthetic. It is 2-bromo-2-chloro-1, 1, 1-trifluoroethane and has the following structural formula:



The specific gravity is 1.872-1.877 at 20° C., and the boiling point (range) is 49° C.-51° C. at 760 mm. Hg. The vapor pressure is 243 mm. Hg at 20° C. The blood/gas coefficient is 2.5 at 37° C., and the olive oil/water coefficient is 220 at 37° C. Vapor concentrations within anesthetic range are nonirritating and have a pleasant odor. FLUOTHANE is nonflammable, and its vapors mixed with oxygen in proportions from 0.5 to 50 per cent (v/v) are not explosive.

FLUOTHANE does not decompose in contact with warm soda lime. When moisture is present, the vapor attacks aluminum, brass, and lead, but not copper. FLUOTHANE is soluble in rubber, some plastics, and similar materials; such materials will deteriorate rapidly in contact with FLUOTHANE vapor or liquid. Stability of FLUOTHANE is maintained by the addition of 0.01 per cent thymol (w/w), and storage is in amber colored bottles.

FLUOTHANE should not be kept indefinitely in vaporizing bottles not specifically designed for its use. It is recommended that vaporizers be emptied at the end of each operating day. Thymol does not volatilize along with FLUOTHANE, and therefore accumulates in the vaporizer, and may, in time, impart a yellow color to the remaining liquid or to wicks in vaporizers. The development of such discoloration may be used as an indicator that the vaporizer should be drained and cleaned, and the discolored FLUOTHANE (halothane) discarded. Accumulation of thymol may be removed by washing with diethyl ether. After cleaning a wick or vaporizer, make certain all the diethyl ether has been removed before reusing the equipment to avoid introducing ether into the system.

Actions. FLUOTHANE is an inhalation anesthetic. Induction and recovery are rapid and depth of anesthesia can be rapidly altered. FLUOTHANE progressively depresses respiration. There may be tachypnea with reduced tidal volume and alveolar ventilation. FLUOTHANE is not an irritant to the respiratory tract, and no increase in salivary or bronchial secretions ordinarily occurs. Pharyngeal and laryngeal reflexes are rapidly obtunded. It causes bronchodilation. Hypoxia, acidosis, or apnea may develop during deep anesthesia.

FLUOTHANE reduces the blood pressure, and frequently decreases the pulse rate. The greater the concentration of the drug, the more evident these changes become. Atropine may reverse the bradycardia. FLUOTHANE does not cause the release of catecholamines from adrenergic stores. FLUOTHANE also causes dilation of the vessels of the skin and skeletal muscles.

Cardiac arrhythmias may occur during FLUOTHANE anesthesia. These include nodal rhythm, AV dissociation, ventricular extrasystoles and asystole. FLUOTHANE sensitizes the myocardial conduction system to the action of epinephrine and norepinephrine, and the combination may cause serious cardiac arrhythmias. FLUOTHANE increases cerebral spinal fluid pressure. FLUOTHANE produces moderate muscular relaxation. Muscle relaxants are used as adjuncts in order to maintain lighter levels of anesthesia. FLUOTHANE augments the action of nondepolarizing relaxants and ganglionic blocking agents. FLUOTHANE is a potent uterine relaxant.

Indications. FLUOTHANE (halothane) is indicated for the induction and maintenance of general anesthesia.

Contraindications. FLUOTHANE should be avoided when a previous exposure was followed by fever and jaundice, or when there was an unexplained postoperative fever.

FLUOTHANE is not recommended for obstetrical anesthesia except when uterine relaxation is required.

Warnings. FLUOTHANE should be used in vaporizers that permit a reasonable approximation of output, and preferably of the calibrated type. The vaporizer should be placed out of circuit in closed circuit rebreathing systems; otherwise overdosage is difficult to avoid. The patient should be closely observed for signs of overdosage, *i.e.*, depression of blood pressure, pulse rate, and ventilation, particularly during assisted or controlled ventilation.

Usage in Pregnancy: Safe use of FLUOTHANE has not been established with respect to possible adverse effects upon fetal development. Therefore, FLUOTHANE should not be used in women where pregnancy is possible and particularly during early pregnancy, unless, in the judgment of the physician, the potential benefits outweigh the unknown hazards to the fetus.

Precautions. The uterine relaxation obtained with FLUOTHANE, unless carefully controlled, may fail to respond to ergot derivatives and oxytocic posterior pituitary extract.

FLUOTHANE increases cerebrospinal fluid pressure. Therefore, in patients with markedly raised intracranial pressure, if FLUOTHANE is indicated, administration should be preceded by measures ordinarily used to reduce cerebrospinal fluid pressure. Ventilation should be carefully assessed, and it may be necessary to assist or control ventilation to insure adequate oxygenation and carbon dioxide removal.

Epinephrine or norepinephrine should be employed cautiously, if at all, during FLUOTHANE (halothane) anesthesia since their simultaneous use may induce ventricular tachycardia or fibrillation.

Nondepolarizing relaxants and ganglionic blocking agents should be administered cautiously, since their actions are augmented by FLUOTHANE.

Adverse Reactions. The following adverse reactions have been reported: hepatic necrosis, cardiac arrest, hypotension, respiratory arrest, cardiac arrhythmias, hyperpyrexia, shivering, nausea, and emesis.

Dosage and Administration. FLUOTHANE may be administered by the nonrebreathing technic, partial rebreathing, or closed technic. The induction dose varies from patient to patient. The maintenance dose varies from 0.5 per cent to 1.5 per cent.

FLUOTHANE may be administered with either oxygen or a mixture of oxygen and nitrous oxide (usually in a 50:50 ratio).

How Supplied. No. 3125—Unit packages of 125 cc. and 250 cc. of halothane stabilized with 0.01% thymol (w/w).

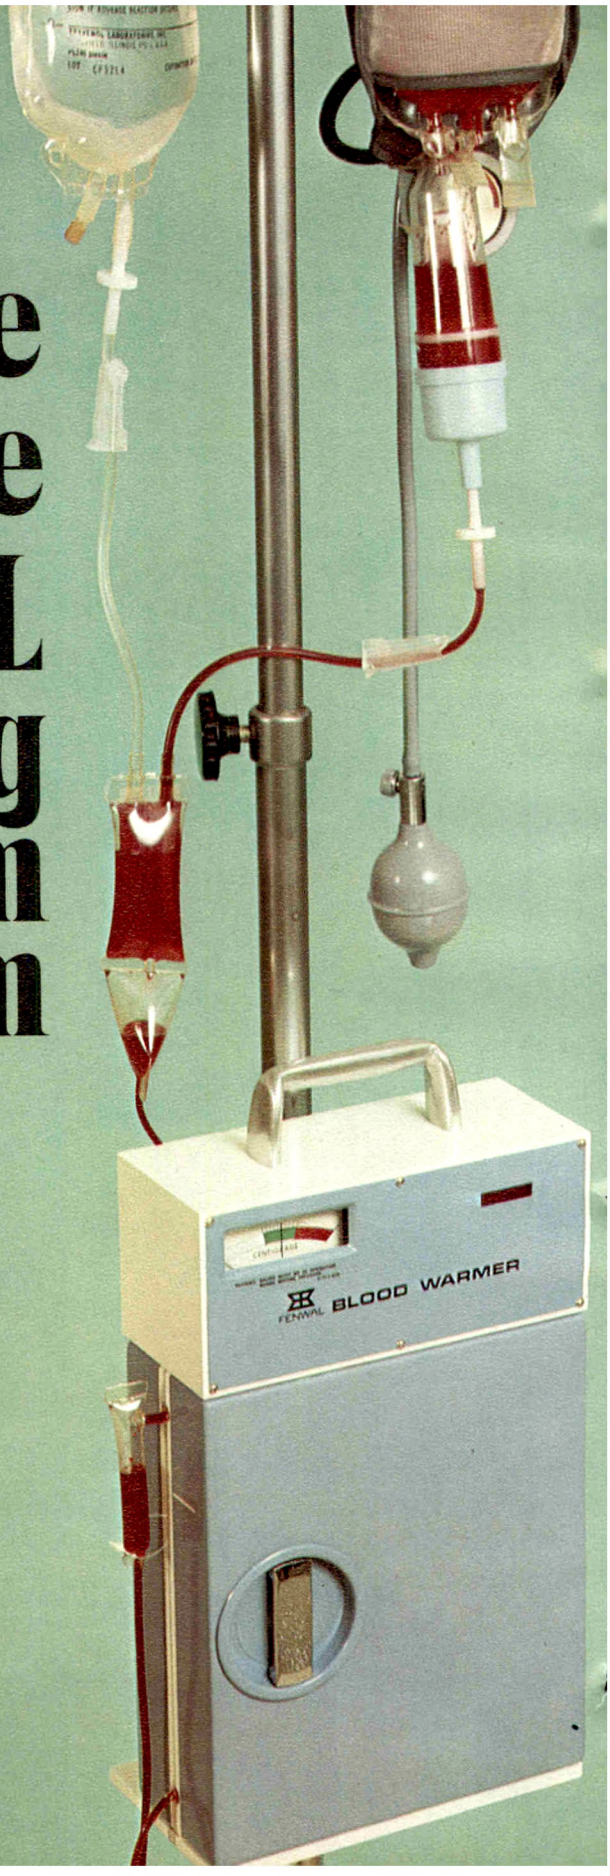
patients

The complete FENWAL operating room system



The Fenwal Dry Heat Blood Warmer is designed for use during single or multiple transfusions when precise regulation of blood temperature and flow rate is indicated. It utilizes a disposable plastic blood-warming pathway.

Fenwal Recipient Sets are available to accommodate your infusion requirements. The Single Lead Set is to be used for the intravenous administration of one unit of whole blood, red cells or plasma. The "Y" Recipient Set is designed to permit dual hookups for simultaneous administration of blood and/or solutions. The Triple Lead Set may be employed in multiple infusion procedures, i.e., blood, solutions, blood components and medication.

The Fenwal Microaggregate Blood Filter is designed to remove microaggregates down to 20 microns in size during intravenous administration of stored whole blood or red cells.

Fenwal Pressure Infusors provide an efficient non-air-dependent method for the rapid infusion of whole blood or red cells.

The Fenwal TYPENEX™ Blood Recipient Identification System ties together the identity of the transfusion candidate, his cross-match request form, blood sample and up to 10 cross-matched units of blood.

The Fenwal Venous Pressure Manometer Set is a disposable, preassembled unit that permits continuous monitoring of the patient's venous pressure while performing one simple hookup.

The Fenwal Platelet Recipient Set is designed specifically for the infusion of fresh blood and pool platelet concentrates.

Our best to you

Fenwal Laboratories has long been identified with innovation in modern blood handling systems. Our knowledge and experience in developing and providing sophisticated blood processing systems have earned a reputation for excellence. Thoroughly researched and tested to meet the demands of the medical profession, you can expect the same quality in Fenwal operating room devices that helped achieve our recognition with the nation's blood banks.

The Fenwal Specialist in your hospital can provide you and the other members of the operating team with completely detailed information on all of our products. Intensive training makes him fully qualified to answer your most involved questions regarding up-to-date blood transfusion procedure. Be sure to see your Fenwal Specialist the next time he visits your department.

Uncommon Endotracheal Tubes From The Most Commonly Known Name In Anesthesia

Now here's a disposable endo tube worthy of the OHIO name!

Uncuffed, or with anatomically designed cuffs for a gentle seal. Clear tubes, Murphy eye, radiopaque tips, depth markings. And a unique inflation and pilot balloon assembly.

OHIO now makes a wide range of sizes. Each tube, sterile packed, for one-patient use.

It's common knowledge that OHIO is the leader in anesthesia equipment. A dependable supplier of inhalation agents and medical gases.

Now, watch us move ahead in disposables. Endo tubes, an anesthesia breathing circuit, filters, masks, airways, suction valves, catheters, tubing . . . And more coming. With many distribution and delivery facilities to keep you supplied.

Write for Catalog # 2604. Or contact your OHIO representative about disposables. For the common good of you and your patients.

The tender touch

These soft, pliable blood pressure cuffs are ideal for use on newborns and infants. Incorporating a Latex bladder, minimizing any chances for skin irritation, and Silicon wrap-around with 12-inch inflating tube. They are secured by the Velcro hook and pile method, with no eyes to hook nor ends to tuck in. They are instantly peeled apart for easy removal.

Cuffs are available in two sizes:
22080 - 1⅜ x 5" (new born)
22081 - 2¼ x 6" (infant)

For additional information write for brochure number 27.

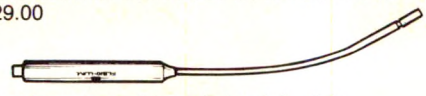
The new standard in patient care

Prism Laryngoscope, designed to simplify difficult intubations. Enables insertion of an endotrocheal tube with an unobstructed line of vision. Packaged sterile and complete with reusable light.

Cat. No. 9041 includes sterile prism Laryngoscope and Laryngolite, Pack/3 $15.50
Cat. No. 9040 Laryngoscope blades only, sterile, Box/10 $29.50
Cat. No. 1022 Laryngolite, designed to provide illumination for Cat. No. 9040, sterile, Box/10 $29.00



Flexi-Lum, box of three lighted, flexible intubation stylettes. High intensity, laryngoscope bulb on tip of 10" flexible shaft. Two long-lasting AA alkaline batteries with on-off backswitch. Reliable, non-flickering performance until batteries are depleted. Excellent for intubation guidelight, emergency anesthesia light or blind intubation procedures.
Cat. No. 3034, 10" flexible shaft, Pack/3 $31.02

concept INC. **We put ideas to work.**
12707 U.S. Highway 19 South
Clearwater, Florida 33516

Laryngeal mirror attachment for 006 penlight. Use for viewing posterior pharynx and larynx when anesthetizing prior to bronchoscopy. Packaged 10 per box.
Cat. No. 1506
1-11 boxes $4.25 each
12 + boxes $4.00 each

Tongue Clamp, patented self-locking ratchet with quick thumb release. Excellent for "grabbing" and holding tongue forward in either emergency or routine anesthesia use. Disposable.

Cat. No. 9000, Box/150 $15.75

Doctor's Six Pak, high-intensity, non-flickering beam, six lights per pack. Batteries not replaceable.
Cat. No. 1006
1-2 Six Paks, $7.00 each
3-5 Six Paks, $6.50 each
6 + Six Paks, $6.00 each

If not available from your dealer, order direct from Concept, Inc.

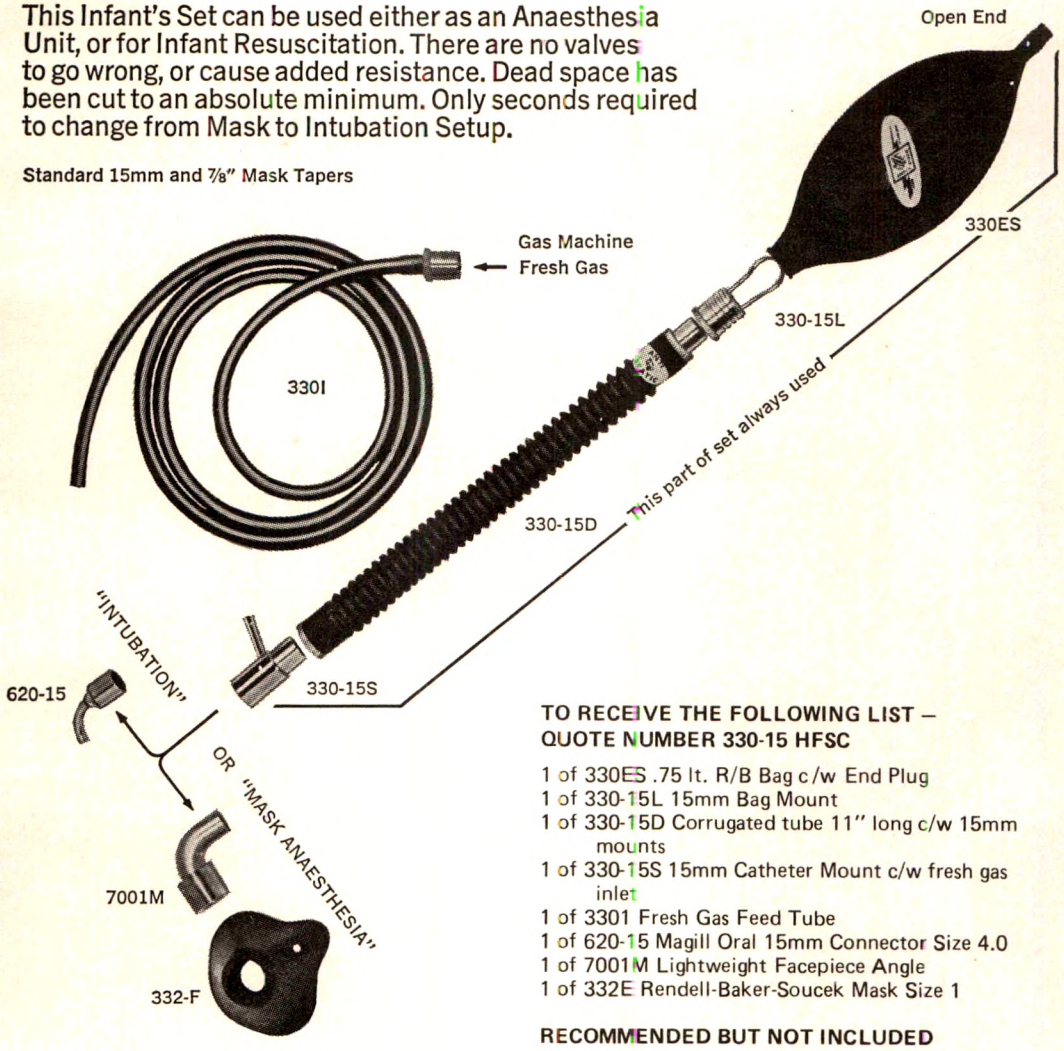
Florida residents add 4% sales tax.

JACKSON-REES MODIFICATION OF AYRE'S T-PIECE

as used by leading children's hospitals

This Infant's Set can be used either as an Anaesthesia Unit, or for Infant Resuscitation. There are no valves to go wrong, or cause added resistance. Dead space has been cut to an absolute minimum. Only seconds required to change from Mask to Intubation Setup.

Standard 15mm and 7/8" Mask Tapers



We recommend you purchase a 330LC Leather Case to store this equipment — prevents loss or damage.

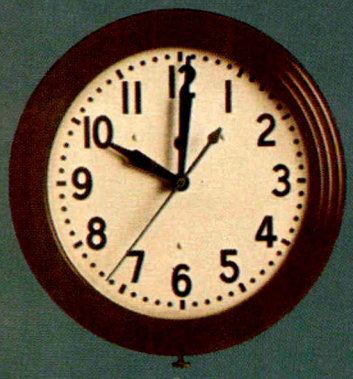
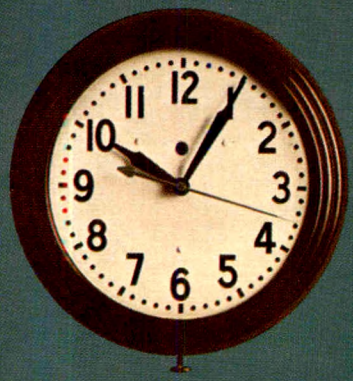
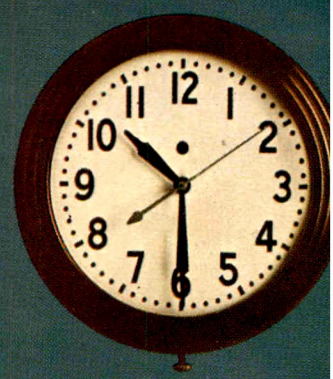
SEND FOR COMPLETE LITERATURE



SUBLIMAZE® (fentanyl) has a uniquely short duration of analgesic action—for more precise control and minimal risk of prolonged narcotic effects.

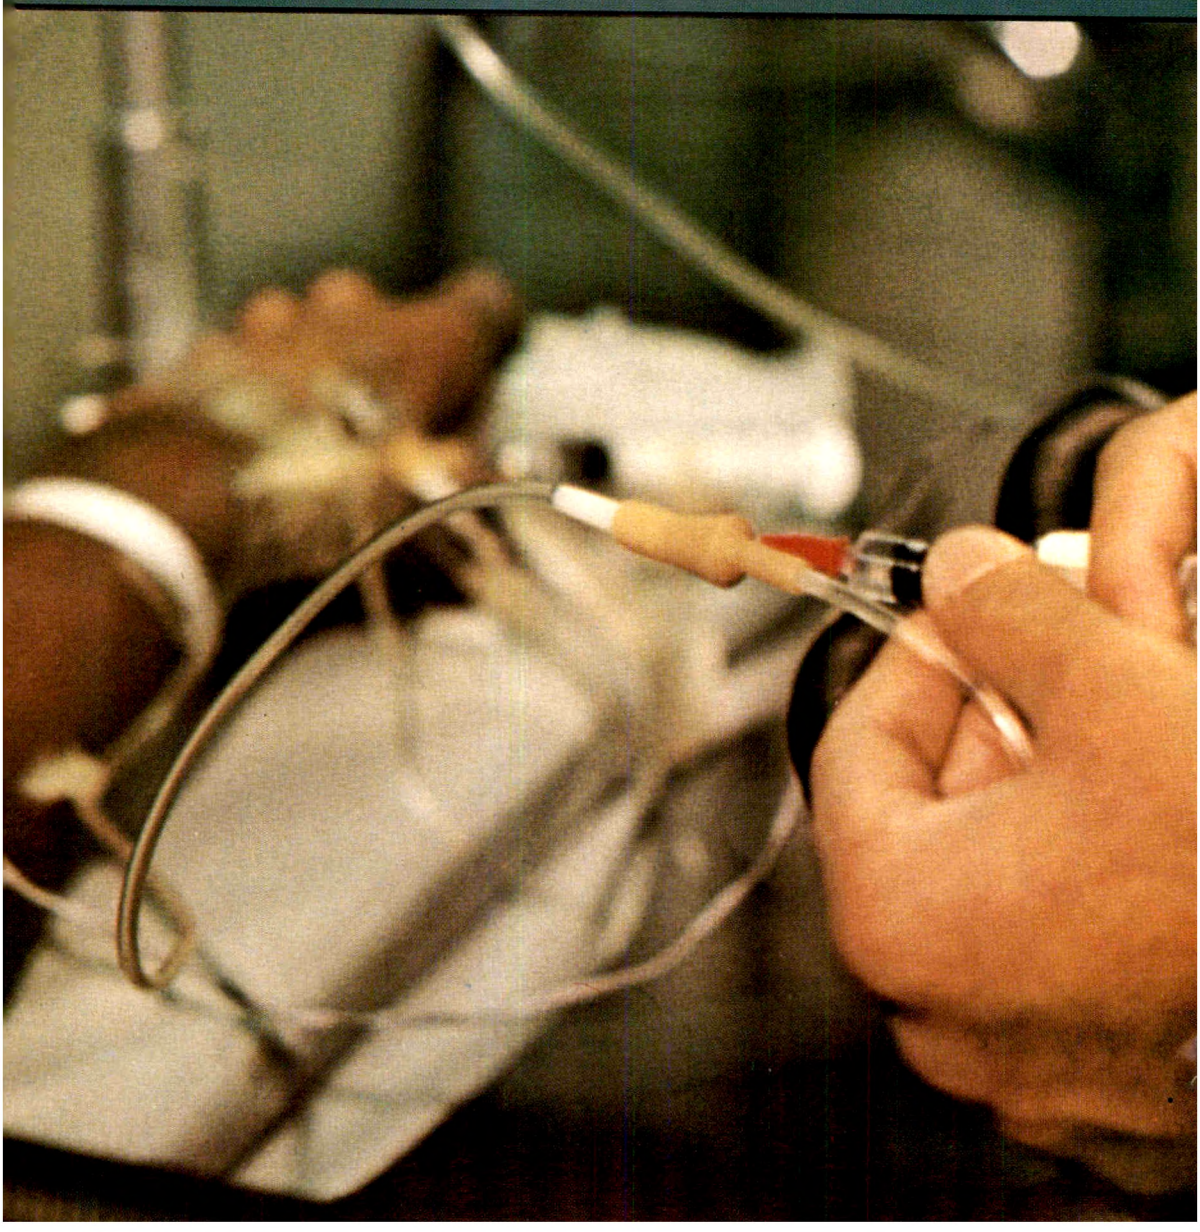


Within 5 minutes I.V., SUBLIMAZE® (fentanyl) reaches its peak analgesic effect.



Within 30 to 60 minutes I.V., the analgesic effect of SUBLIMAZE® (fentanyl) is almost completely dissipated.†

† Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with large doses, multiple doses or use of postoperative narcotic analgesics.



For potent narcotic analgesic action with rapid onset and short duration:

SUBLIMAZE fentanyl provides profound analgesia without hypnosis and with little or no sedation. With this analgesia as a foundation, it is possible to use light general anesthesia in most cases.

SUBLIMAZE fentanyl is particularly suited for maintenance of analgesia after INNOVAR® injection* has been used for induction. It may also be used preoperatively, during surgery with any common general or regional anesthetic agent, and in the immediate postoperative period whenever the need for potent analgesic action arises.

SUBLIMAZE fentanyl is available both alone and as a component of INNOVAR injection.*

*INNOVAR injection is composed of a 50:1 mixture of droperidol 2.5 mg./cc. and fentanyl 0.05 mg./cc., with lactic acid for adjustment of pH to 3.5 ± 0.3.

SUBLIMAZE® (fentanyl) offers:

☐ Almost immediate analgesia—peak effect within 5 minutes I.V., 8 minutes I.M.

☐ Short duration of analgesic action—30 to 60 minutes with a single I.V. dose of up to 0.1 mg. (Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.)

☐ No evidence of liver, heart, or kidney toxicity—expecially valuable in poor-risk patients. However, the drug should be administered cautiously in the presence of liver or kidney dysfunction or cardiac arrhythmias, and the dose should be appropriately reduced in poor-risk patients.

☐ Immediate reversibility by narcotic antagonists.

☐ Little or no histamine release—decreasing the risk of cardiovascular instability.

☐ Minimal emetic effect—has been used successfully to prepare nonfasting patients for awake intubation.

☐ Prevention or reversal of emergence delirium and tachypnea.

SUBLIMAZE® Ⓒ II (fentanyl) injection

0.05 mg./cc. as the citrate.
Warning: May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0—7.5

INNOVAR® injection and SUBLIMAZE® (fentanyl) injection are available for use only upon direction of a physician. For information relating to Contraindications, Warnings, Precautions and Adverse Reactions for SUBLIMAZE fentanyl, please turn page.

© McNeil Laboratories, Inc., 1974

SUBLIMAZE® (fentanyl) injection

Description
Each cc. contains:
Fentanyl as the citrate.....0.05 mg.
Warning—May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0–7.5
FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY.

Actions SUBLIMAZE fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. SUBLIMAZE fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. SUBLIMAZE fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays and skin wheal testing in man, as well as *in vivo* testing in dogs, indicate that histamine release rarely occurs with SUBLIMAZE fentanyl.

SUBLIMAZE fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of SUBLIMAZE fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours.

Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics it may be considerably longer than the analgesic effect.

Indications SUBLIMAZE fentanyl is indicated:
—for analgesic action of short duration during the anesthetic periods, premedication, induction, and maintenance, and in the immediate postoperative period (recovery room) as the need arises.
—for use as a narcotic analgesic supplement in general or regional anesthesia.
—for administration with a neuroleptic such as INAPSINE® (droperidol) injection as an anesthetic premedication,for the induction of anesthesia and as an adjunct in the maintenance of general and regional anesthesia.

Contraindications SUBLIMAZE fentanyl is contraindicated in patients who are hypersensitive to the drug.

Warnings PATIENTS WHO HAVE RECEIVED *SUBLIMAZE* FENTANYL SHOULD HAVE APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

If SUBLIMAZE fentanyl is administered with a tranquilizer such as INAPSINE droperidol, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action. In addition, when such a combination is used *fluids and other countermeasures to manage hypotension should be available.*

As with other potent narcotics, the respiratory depressant effect of SUBLIMAZE fentanyl persists longer than the measured analgesic effect. The total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, should be used in reduced doses initially, as low as 1/4 to 1/3 those usually recommended. A neuromuscular blocking agent compatible with the patient's condition may be required to control muscle rigidity which may develop with the use of SUBLIMAZE fentanyl.

Drug Dependence: SUBLIMAZE fentanyl can produce drug dependence of the morphine type and therefore has the potential for being abused.

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl in this regard has not been established, the use of SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: SUBLIMAZE fentanyl should be used with caution in patients who may be particularly susceptible to respiratory depression, such as comatose patients who may have a head injury or brain tumor. In addition, SUBLIMAZE fentanyl may obscure the clinical course of patients with head injury.

Usage in Children: The safety of SUBLIMAZE fentanyl in children younger than two years of age has not been established.

Usage in Pregnancy: The safe use of SUBLIMAZE fentanyl has not been established with respect to possible adverse effects upon fetal development. Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

Precautions *The initial dose of SUBLIMAZE fentanyl should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal a thesia and some peridural anesthetics, can alter respiratio blocking intercostal nerves. Through other mechanisms (see tions) SUBLIMAZE fentanyl can also alter respiration. W SUBLIMAZE fentanyl is used to supplement these forms of a thesia, the anesthetist should be familiar with the physiolog alterations involved, and be prepared to manage them in patients selected for these forms of anesthesia. When used wi tranquilizer such as INAPSINE droperidol, blood pressure ma altered and hypotension can occur.

Vital signs should be monitored routinely.

SUBLIMAZE fentanyl should be used with caution in patie with chronic obstructive pulmonary disease, patients with creased respiratory reserve, and others with potentially comp mised respiration. In such patients, narcotics may addition decrease respiratory drive and increase airway resistance. Dur anesthesia, this can be managed by assisted or controlled resp tion. Postoperatively, respiratory depression caused by narc analgesics can be reversed by narcotic antagonists (levallorph nalorphine, and naloxone; consult individual prescribing infor tion before using). Should respiration be compromised by mus rigidity, assisted or controlled respiration and possibly a neu muscular blocking agent will be required. The occurrence muscle rigidity is related to the speed of intravenous injection a the incidence can be reduced by slow intravenous injection.

When a tranquilizer such as INAPSINE droperidol is used w SUBLIMAZE fentanyl, pulmonary arterial pressure may be creased. This fact should be considered by those who cond diagnostic and surgical procedures where interpretation of p monary arterial pressure measurements might determine fi management of the patient.

Other CNS depressant drugs (e.g. barbiturates, tranquilize narcotics, and general anesthetics) will have additive or potent ing effects with SUBLIMAZE fentanyl. When patients have ceived such drugs, the dose of SUBLIMAZE fentanyl required be less than usual. Likewise, following administration SUBLIMAZE fentanyl the dose of other CNS depressant dru should be reduced.

SUBLIMAZE fentanyl should be administered with caution patients with liver and kidney dysfunction because of the imp tance of these organs in the metabolism and excretion of drug

SUBLIMAZE fentanyl may produce bradycardia, which m be treated with atropine; however, SUBLIMAZE fentanyl sho be used with caution in patients with cardiac bradyarrhythmias

When SUBLIMAZE fentanyl is used with a tranquilizer such INAPSINE droperidol, hypotension can occur. If this occurs t possibility of hypovolemia should also be considered and ma aged with appropriate parenteral fluid therapy. Repositioning t patient to improve venous return to the heart should be co sidered when operative conditions permit. Care should be ex cised in moving and positioning of patients because of t possibility of orthostatic hypotension. If volume expansion w fluids plus other countermeasures do not correct hypotension, t administration of pressor agents other than epinephrine should considered. Because of the alpha-adrenergic blocking action INAPSINE droperidol, epinephrine may paradoxically decrea the blood pressure in patients treated with INAPSINE droperid

Adverse Reactions As with other narcotic analgesics, the m common serious adverse reactions reported to occur w SUBLIMAZE fentanyl are respiratory depression, apnea, musc lar rigidity, and bradycardia; if these remain untreated, respirat arrest, circulatory depression or cardiac arrest could occur.

Other adverse reactions that have been reported are hy tension, dizziness, blurred vision, nausea, emesis, laryngospas and diaphoresis.

When a tranquilizer such as INAPSINE droperidol is used w SUBLIMAZE fentanyl, the following adverse reactions can occ chills and/or shivering, restlessness, and postoperative hallucir tory episodes (sometimes associated with transient periods mental depression); extrapyramidal symptoms (dystonia, akat sia, and oculogyric crisis) have been observed up to 24 ho postoperatively. When they occur, extrapyramidal symptoms c usually be controlled with antiparkinson agents. Postoperati drowsiness is also frequently reported following the use INAPSINE droperidol.

Overdosage ***Manifestations:*** The manifestations of SUBLIMAZ fentanyl overdosage are an extension of its pharmacologic actio ***Treatment:*** In the presence of hypoventilation or apnea, oxyg should be administered and respiration should be assisted controlled as indicated. A patent airway must be maintained; oropharyngeal airway or endotracheal tube might be indicated depressed respiration is associated with muscular rigidity, intravenous neuromuscular blocking agent might be required facilitate assisted or controlled respiration. The patient should carefully observed for 24 hours; body warmth and adequate flu intake should be maintained. If hypotension occurs and is seve or persists, the possibility of hypovolemia should be consider and managed with appropriate parenteral fluid therapy. A speci narcotic antagonist such as nalorphine, levallorphan, or naloxo should be available for use as indicated to manage respirat depression. This does not preclude the use of more immedia countermeasures. Consult the package insert for the individu narcotic antagonists for details about use.

How Supplied SUBLIMAZE® (fentanyl) injection is supplied ir cc. (**NDC** 0045-0180-03) and 5 cc. (**NDC** 0045-0180-05) ampuls, packages of 12.

IMPORTANT: Complete dosage information is available in ins which accompanies each package (or on request). The drug is ava able only upon direction of a physician.

RALS POWER UNIT

...INSTANT ATOMIZATION FOR FAST TOPICAL ANESTHESIA

Fast, measured topical anesthesia is ready at your finger tips in a Rals Power Unit. Forget about pumping bulbs, uneven atomization, and limited spraying duration. The Rals Power Unit uses a non-toxic propellant, dichlorodifluoromethane (freon) to activate standard DeVilbiss Atomizers No's. 151, 152 and 163. Instantly, a fine mistlike spray is produced. A graduated solution vial is available for measuring the amount of solution administered.

The Rals Power Unit has been proven effective in cocainization prior to endotracheal intubation, endoscopic instrumentation, laryngotracheal insufflation, and in a variety of nose and throat procedures.

Rals Power Unit #168 are supplied six to a box with adaptor top and metal base. Illustration shows #152 atomizer. All styles in stock.

PROFESSIONAL INSTRUMENTS COMPANY MODEL NS-2 * PERIPHERAL NERVE STIMULATOR

MONITORS EFFECTS OF SKELETAL MUSCLE RELAXANTS ON THE NEUROMUSCULAR JUNCTION, DETECTING ABNORMAL RESPONSE TO MUSCLE RELAXANTS AND DISTINGUISHES BETWEEN DEPOLARIZING AND NON-DEPOLARIZING BLOCKADE.

THE MODEL NS-2

- ☐ **DELIVERS** STIMULI AT 5 SECOND INTERVALS. ONE OR FIFTY PULSES-PER-SECOND MAY BE SELECTED BY MOMENTARY PUSH-BUTTON SWITCHES.
- ☐ **OUTPUT** IS A MONOPHASIC SQUARE WAVE PULSE HAVING A RISE AND FALL TIME OF LESS THAN ONE MICROSECOND. AMPLITUDE OF PULSE IS LINEARLY ADJUSTABLE.
- ☐ **SOLID STATE**, RUGGED, BATTERY POWERED, PORTABLE AND LIGHTWEIGHT. THE USE OF INTEGRATED CIRCUITS ENSURES MAXIMUM RELIABILITY.
- ☐ **IT IS** THE RESULT OF AN AGGRESSIVE, CONTINUING RESEARCH AND DEVELOPMENT PROGRAM IN NERVE STIUMLATORS AND OTHER ELECTRONIC PRODUCTS BY PROFESSIONAL INSTRUMENTS COMPANY.

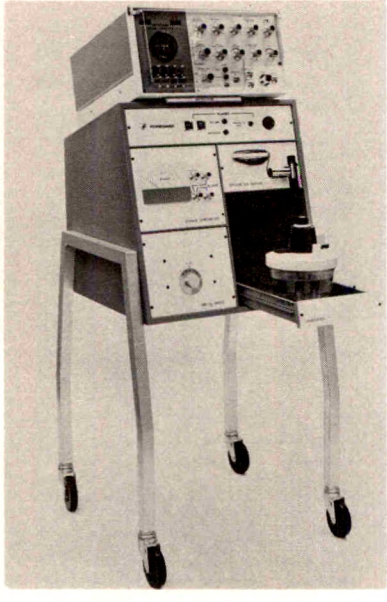
SOMETHING NEW

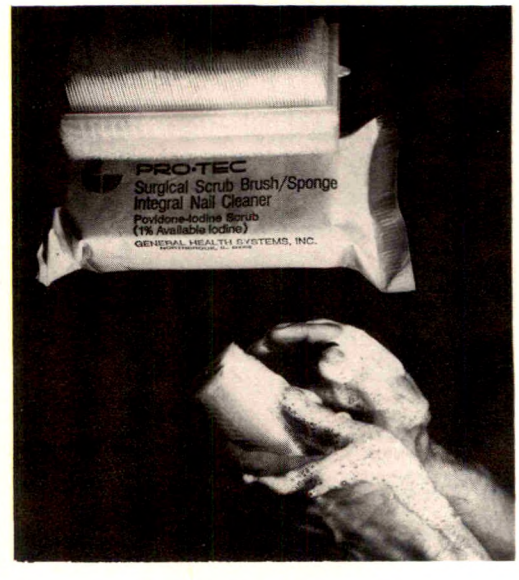


Air Products and Chemicals, Inc., Medical Products Division, Allentown, Pennsylvania, have a new volume ventilator called the FOREGGER® 210 Volume Ventilator.

It features an IMV (Inter-Mandatory Ventilation) function for weaning patients from mechanical ventilation and an I:E Ratio (Inspiratory:Expiratory) control that can be preset and maintained (1:1 to 1:4) over a variety of Tidal volumes and breathing rates. Other functions include PEEP, Assist, Inspiratory Pause, Sigh, and Multiple Sigh. A new high-output, minimal-noise compressor that fits between the ventilator's legs is available.

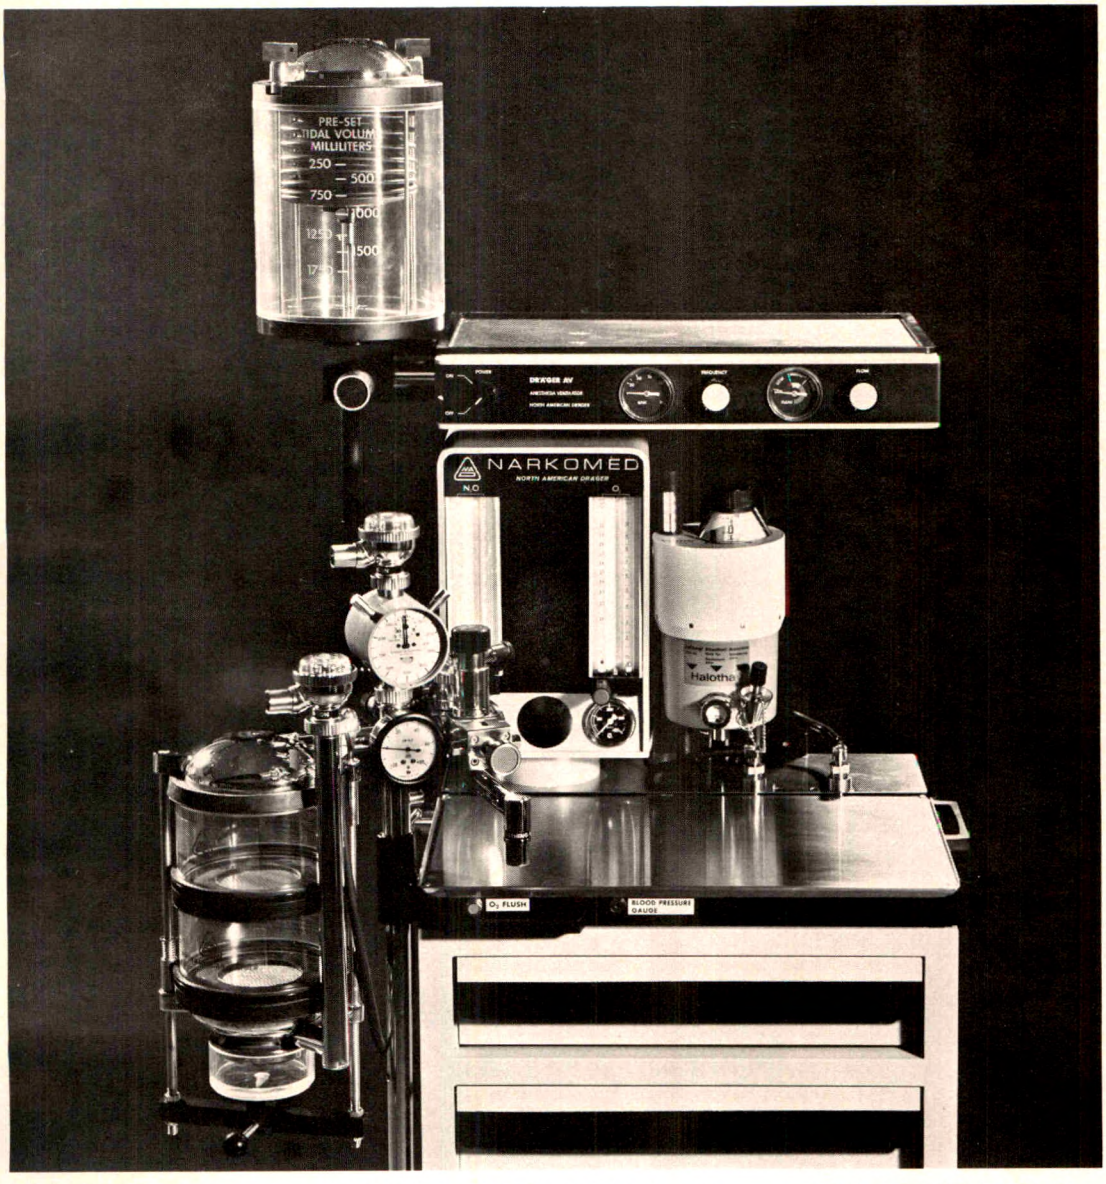
An extensive battery of audio and visual alarms designed to monitor the units' multi-functions, power-input and patient life-support systems is part of the new Foregger Ventilator.

★ ★ ★



General Health Systems, Inc., Northbrook, Illinois, have available the Pro-tec Disposable Scrub Brush and Sponge. Each scrub unit contains a bristle brush, foaming sponge and nail cleaner packaged in a tear-open pack.

NARKOMED



TOTAL ANESTHESIA SYSTEM

NARKOMED, a refreshing new concept in anesthesia machine design and styling, incorporating a contemporary anesthesia dispensing system with a built-in fluidic anesthesia ventilator and the widest variety of options.

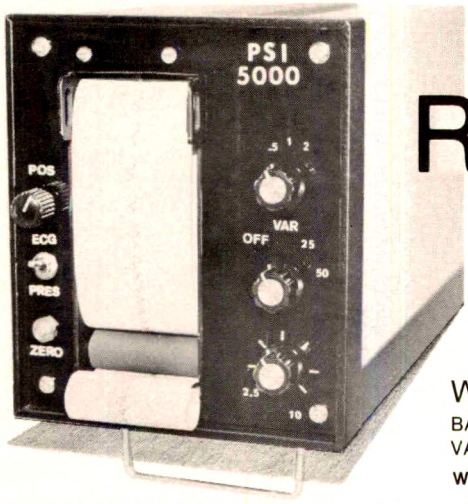
INTRODUCING



the PSI 5000 Recorder

MEASURES & RECORDS

ECG • PULSE •
VITAL PRESSURES

- ARTERIAL
- VENOUS
- INTERCRANIAL
- PULMONARY WEDGE

WHEN VERSATILITY COUNTS

BATTERY OPERATION, VARIABLE AMPLITUDES
VARIABLE SPEEDS AND TREND - 2.5 to 50 mm/Sec.

Whenever precise permanent copies are essential.

The PSI 5000 Recorder is a portable, battery operated, self-contained unit for use in most heart, lung, and blood pressure measurements. The PSI 5000 meets AHA specifications for electrocardiography, assuring superior performance in any application requiring high frequency response. The pen stylus is held in a stress-free mount on a titanium arm to provide exceptional life. It is capable of sustaining up to 1000 G's acceleration. A fully charged battery will provide up to four hours continuous operation.

51ST CONGRESS

International Anesthesia Research Society

MARCH 6-10, 1977

DIPLOMAT RESORT AND COUNTRY CLUBS
HOLLYWOOD, FLORIDA

Minute by minute

In those places where new concepts are readily accepted and fresh ideas in medical science generated, the BOC Medishield Wright Respiration Monitor is established as an important aid to health care. In the progressive environment of the theatre and ICU, the Wright Respiration Monitor has gained immediate acceptance.

The output of the Monitor can be connected to external recording apparatus. This trace of tidal and minute volumes provides information of diagnostic value. Therefore, the innovation enhances the value of apparatus as an aid to the investigation of patterns of respiration – of individual patients – and as a research tool of general application.

Features include:

Direct read-out of minute volume.

Mobility of Monitor. Choice of battery or mains supply.

Remote from point of measurement. Distant continuous monitoring.

Convenient, clearly labelled push-button controls.

Clear precise display of information – instantaneously assimilated.

Versatility – Safety – Reliability

McGILL UNIVERSITY

ANNUAL REVIEW COURSE IN ANAESTHESIA - 1976

May 24-28, 1976

This course is directed towards senior residents, candidates preparing for higher examinations and full time specialist anesthesiologists. The course content has been chosen to review important areas of scientific background and clinical practice, with emphasis on recent developments.

Teaching personnel consist of senior members of the McGill Faculty of Medicine together with a most distinguished guest faculty.

The meeting is held in a relaxed and attractive setting in McGill University.

FEE: $200.00
$100.00 (residents)

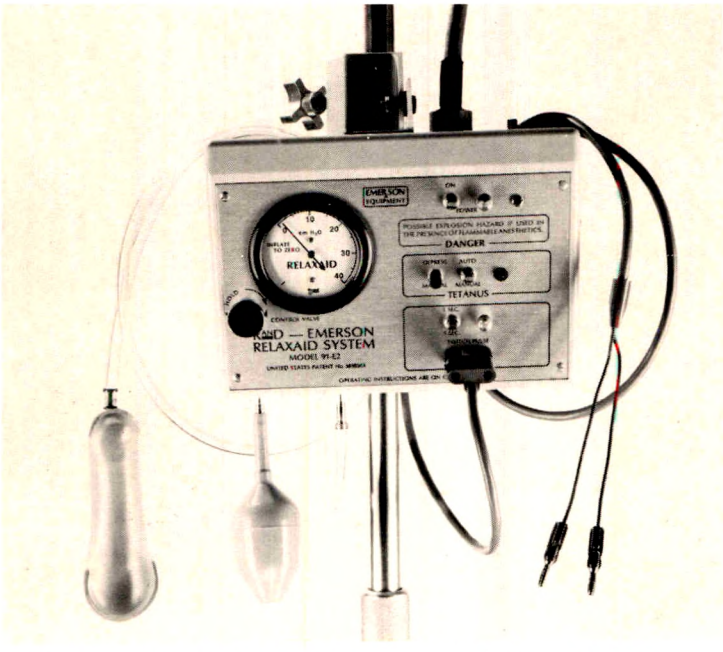
R AND D-EMERSON RELAXAID™



for CORRECT RELAXANT DOSAGE—
AVOIDANCE OF OVERDOSE—
PROMPT RECOVERY—

The stimulator is programed to deliver pulses, through electrodes, to the ulnar nerve. A flexible pneumatic bulb is placed in the patient's hand, with his fingers held against it by tape. The bulb is then air-filled to a pressure of 20 cm. H_2O. As the fingers flex, even slightly, compression of the bulb is registered on an aneroid gauge. The pattern of these responses keeps the anesthetist informed of the relaxant's effectiveness.

The more precise monitoring provided by the RELAXAID™ enables relaxant levels to be kept adequate but without overdose. During recovery the RELAXAID™ shows the return of strength to the patient's muscles.

If You're Confused About O.R. Pollution, Cut It Out.

Get a compilation of data on the problems of trace anesthetic gas and OR pollution control. Send for our Positive Response Program.

Besides reports and studies to help you put the problem in perspective, our "PRP" plan of action provides an up-to-date look at our products which help you detect and scavenge trace gas in your OR. Key to our program is the Foregger 410 N_2O Trace Gas Monitor, a basic requirement for any efficient trace gas monitoring program. It's designed to provide rapid and continuous sampling of the OR air you breathe.

The machine has two sensing modes—Monitor (0-100 ppm) and Leak Test (0-1,000 ppm). The first mode continuously monitors the ambient air through the gas inlet of the machine. The second permits probing of local concentrations and sounds a repetitive burst alarm as the gas concentration increases.

In short, the Foregger 410 N_2O Trace Gas Monitor is a logical first step in solving your OR pollution problem. And there's more. The Scaveng-OR™ Gas Evacuator System, the Protect-OR™ Filter, Wall Suction Systems, and Air-CARE™ Preventive Maintenance Service.

Based on current data, it's likely that routine monitoring of pollution levels and scavenging of waste anesthetic gases will soon be standard Operating Room procedure. We're ready to help you now.

Fill out this ad coupon or ask our Representative for a Foregger PRP Folder. You'll get the problem in perspective and a plan of action to help correct it.

In 16 years of use in the United States, FLUOTHANE (halothane) has been administered over 100 million times in a wide variety of surgical procedures. 100 million . . . extensive usage and evaluation that attests to FLUOTHANE as the most widely used inhalant anesthetic.

Since it was first introduced, over 4,000 papers worldwide have been published, ranging from review articles to in-depth studies. 4,000 papers . . . a bibliographic record of note on the most widely used inhalant anesthetic.

In a continuing program of informational services on anesthesiology, Ayerst provides printed and audiovisual aids reflecting the opinions and experiences of recognized authorities in the field. These include the highly regarded series on *Anesthesia Rounds* and *Clinical Aspects of Anesthesiology*, as well as several films of educational value—all available through your Ayerst Representative.

FLUOTHANE® (HALOTHANE) ...OVER 100 MILLION ADMINISTRATIONS

- nonflammable, nonexplosive
- permits use of high concentrations of oxygen
- allows free use of cautery for more adequate control of bleeding
- minimal odor facilitates smooth, rapid induction, reduces patient distress
- early obtundation of pharyngeal and laryngeal reflexes facilitates intubation
- lessens airway problems
- permits rapid adjustment of depth of anesthesia
- emergence is rapid and tranquil with quick recovery of protective reflexes
- minimal nausea and vomiting, shorter recovery room stay

Ayerst®

See last page of advertisement for prescribing information.

FLUOTHANE®

brand of halothane

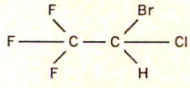
the most widely used inhalant anesthetic

from **Ayerst**

for precision, experience, quality, and service

(Complete text of package circular.)

Description. FLUOTHANE, brand of halothane, is an inhalation anesthetic. It is 2-bromo-2-chloro-1, 1, 1-trifluoroethane and has the following structural formula:



The specific gravity is 1.872-1.877 at 20° C., and the boiling point (range) is 49° C.-51° C. at 760 mm. Hg. The vapor pressure is 243 mm. Hg at 20° C. The blood/gas coefficient is 2.5 at 37° C., and the olive oil/water coefficient is 220 at 37° C. Vapor concentrations within anesthetic range are nonirritating and have a pleasant odor. FLUOTHANE is nonflammable, and its vapors mixed with oxygen in proportions from 0.5 to 50 per cent (v/v) are not explosive.

FLUOTHANE does not decompose in contact with warm soda lime. When moisture is present, the vapor attacks aluminum, brass, and lead, but not copper. FLUOTHANE is soluble in rubber, some plastics, and similar materials; such materials will deteriorate rapidly in contact with FLUOTHANE vapor or liquid. Stability of FLUOTHANE is maintained by the addition of 0.01 per cent thymol (w/w), and storage is in amber colored bottles.

FLUOTHANE should not be kept indefinitely in vaporizing bottles not specifically designed for its use. It is recommended that vaporizers be emptied at the end of each operating day. Thymol does not volatilize along with FLUOTHANE, and therefore accumulates in the vaporizer, and may, in time, impart a yellow color to the remaining liquid or to wicks in vaporizers. The development of such discoloration may be used as an indicator that the vaporizer should be drained and cleaned, and the discolored FLUOTHANE (halothane) discarded. Accumulation of thymol may be removed by washing with diethyl ether. After cleaning a wick or vaporizer, make certain all the diethyl ether has been removed before reusing the equipment to avoid introducing ether into the system.

Actions. FLUOTHANE is an inhalation anesthetic. Induction and recovery are rapid and depth of anesthesia can be rapidly altered. FLUOTHANE progressively depresses respiration. There may be tachypnea with reduced tidal volume and alveolar ventilation. FLUOTHANE is not an irritant to the respiratory tract, and no increase in salivary or bronchial secretions ordinarily occurs. Pharyngeal and laryngeal reflexes are rapidly obtunded. It causes bronchodilation. Hypoxia, acidosis, or apnea may develop during deep anesthesia.

FLUOTHANE reduces the blood pressure, and frequently decreases the pulse rate. The greater the concentration of the drug, the more evident these changes become. Atropine may reverse the bradycardia. FLUOTHANE does not cause the release of catecholamines from adrenergic stores. FLUOTHANE also causes dilation of the vessels of the skin and skeletal muscles.

Cardiac arrhythmias may occur during FLUOTHANE anesthesia. These include nodal rhythm, AV dissociation, ventricular extrasystoles and asystole. FLUOTHANE sensitizes the myocardial conduction system to the action of epinephrine and norepinephrine, and the combination may cause serious cardiac arrhythmias. FLUOTHANE increases cerebral spinal fluid pressure. FLUOTHANE produces moderate muscular relaxation. Muscle relaxants are used as adjuncts in order to maintain lighter levels of anesthesia. FLUOTHANE augments the action of nondepolarizing relaxants and ganglionic blocking agents. FLUOTHANE is a potent uterine relaxant.

Indications. FLUOTHANE (halothane) is indicated for the induction and maintenance of general anesthesia.

Contraindications. FLUOTHANE should be avoided when a previous exposure was followed by fever and jaundice, or when there was an unexplained postoperative fever.

FLUOTHANE is not recommended for obstetrical anesthesia except when uterine relaxation is required.

Warnings. FLUOTHANE should be used in vaporizers that permit a reasonable approximation of output, and preferably of the calibrated type. The vaporizer should be placed out of circuit in closed circuit rebreathing systems; otherwise overdosage is difficult to avoid. The patient should be closely observed for signs of overdosage, *i.e.*, depression of blood pressure, pulse rate, and ventilation, particularly during assisted or controlled ventilation.

Usage in Pregnancy: Safe use of FLUOTHANE has not been established with respect to possible adverse effects upon fetal development. Therefore, FLUOTHANE should not be used in women where pregnancy is possible and particularly during early pregnancy, unless, in the judgment of the physician, the potential benefits outweigh the unknown hazards to the fetus.

Precautions. The uterine relaxation obtained with FLUOTHANE, unless carefully controlled, may fail to respond to ergot derivatives and oxytocic posterior pituitary extract.

FLUOTHANE increases cerebrospinal fluid pressure. Therefore, in patients with markedly raised intracranial pressure, if FLUOTHANE is indicated, administration should be preceded by measures ordinarily used to reduce cerebrospinal fluid pressure. Ventilation should be carefully assessed, and it may be necessary to assist or control ventilation to insure adequate oxygenation and carbon dioxide removal.

Epinephrine or norepinephrine should be employed cautiously, if at all, during FLUOTHANE (halothane) anesthesia since their simultaneous use may induce ventricular tachycardia or fibrillation.

Nondepolarizing relaxants and ganglionic blocking agents should be administered cautiously, since their actions are augmented by FLUOTHANE.

Adverse Reactions. The following adverse reactions have been reported: hepatic necrosis, cardiac arrest, hypotension, respiratory arrest, cardiac arrhythmias, hyperpyrexia, shivering, nausea, and emesis.

Dosage and Administration. FLUOTHANE may be administered by the nonrebreathing technic, partial rebreathing, or closed technic. The induction dose varies from patient to patient. The maintenance dose varies from 0.5 per cent to 1.5 per cent.

FLUOTHANE may be administered with either oxygen or a mixture of oxygen and nitrous oxide (usually in a 50:50 ratio).

How Supplied. No. 3125—Unit packages of 125 cc. and 250 cc. of halothane stabilized with 0.01% thymol (w/w).

Nesacaine®
(Chloroprocaine Hydrochloride)

1% and 2% solution in 30-ml. multiple-dose vials

For Infiltration and Regional Anesthesia

Nesacaine®-CE
(Chloroprocaine Hydrochloride)

2% and 3% solution in 30-ml. single-dose vials

For Caudal and Epidural Anesthesia

INDICATIONS

NESACAINE in multiple dose vials and NESACAINE-CE in single dose vials without preservatives are indicated for production of local anesthesia by infiltration injection and nerve block.*

*NESACAINE in multiple dose vials with preservatives is not to be used for caudal or epidural anesthesia. NESACAINE-CE contains no preservatives and the unused portion must be discarded after initial use.

CONTRAINDICATIONS

NESACAINE and NESACAINE-CE are contraindicated in patients hypersensitive to drugs of the PABA ester group. Central nervous system disease is generally considered a contraindication to caudal or epidural nerve block.

WARNINGS

RESUSCITATIVE EQUIPMENT AND DRUGS SHOULD BE IMMEDIATELY AVAILABLE WHEN ANY LOCAL ANESTHETIC IS USED. As NESACAINE-CE contains no preservative, discard unused drug remaining in vial after initial use. Equipment and drugs necessary for the treatment of inadvertent intravascular injection, intrathecal injection, or excessive dosage should be immediately available.

Usage in Pregnancy: Safe use of chloroprocaine hydrochloride has not been established with respect to adverse effects upon fetal development. Therefore, it should not be used in women of childbearing potential unless in the judgment of the physician the potential benefits outweigh the unknown hazards. In obstetrics, if vasoconstrictor drugs are used either to correct hypotension or are added to the local anesthetic solution, the obstetrician should be warned that some oxytocic drugs may cause severe persistent hypertension and even rupture of a cerebral blood vessel may occur during the post partum period.

Solutions containing vasoconstrictors, particularly epinephrine and norepinephrine, should be used with extreme caution in patients receiving certain antidepressants such as MAO inhibitors, and tricyclic compounds since a severe prolonged hypertension may occur.

PRECAUTIONS

The lowest dosage that results in effective anesthesia should be used to avoid high plasma levels and serious undesirable systemic side effects. Tolerance varies with the status of the patient. Debilitated patients, elderly patients, acutely ill patients, and children should be given reduced doses commensurate with their age and physical status.

Solutions containing vasoconstrictors should be used cautiously in the presence of disease which may adversely affect the patient's cardiovascular system.

Chloroprocaine hydrochloride should be employed cautiously in persons with known drug allergies or sensitivities.

The decision whether or not to use local anesthesia in the following conditions depends on the physician's appraisal of the advantages as opposed to the risk:

Paracervical block when fetal distress is anticipated or when predisposing factors causative of fetal distress are present (i.e., toxemia, prematurity, diabetes, etc.). Injection of solutions containing epinephrine in areas where the blood supply is limited (i.e., ears, nose, digits, etc.) or when peripheral vascular disease is present.

ADVERSE REACTIONS

Adverse reactions result from high plasma levels due to rapid absorption, inadvertent intravascular injection or excessive dosage. Hypersensitivity, idiosyncrasy, or diminished tolerance are other causes of reactions. Reactions due to overdosage (high plasma levels) are systemic and involve the central nervous system and the cardiovascular system.

Reactions involving the central nervous system are characterized by excitation and/or depression. Nervousness, dizziness, blurred vision or tremors may occur followed by drowsiness, convulsions, unconsciousness and possibly respiratory arrest. Since excitement may be transient or absent, the first manifestations may be drowsiness merging into unconsciousness and respiratory arrest.

Reactions involving the cardiovascular system include depression of the myocardium, hypotension, bradycardia and even cardiac arrest.

Treatment of a patient with toxic manifestations consists of maintaining an airway, and supporting ventilation using oxygen and assisted or controlled respiration as required. Supportive treatment of the cardiovascular system consists of using vasopressors, preferably those that stimulate the myocardium (e.g., ephedrine) and intravenous administration in small increments of an ultrashort acting barbiturate (i.e., thiopental, thiamylal) or a short acting barbiturate if these are not available (secobarbital, pentobarbital) or a short acting muscle relaxant (succinylcholine), together with oxygen. Muscle relaxants and intravenous barbiturates should be used only by those familiar with their use.

Allergic reactions are characterized by cutaneous lesions, urticaria, edema and other manifestations of allergy. The detection of sensitivity by skin testing is of doubtful value.

DOSAGE AND ADMINISTRATION

The maximum single recommended doses of chloroprocaine hydrochloride are: without epinephrine, 800 mg.; with epinephrine (1:200,000), 1000 mg. The recommended dosage is based on requirements for the average adult and should be reduced for elderly or debilitated patients and children.

The recommended doses given below serve only as a guide to the amount of anesthetic required for most routine procedures.

1. INFILTRATION AND NERVE BLOCK (NESACAINE)

Type of Block	Volume	Concentration
Occipital	3-5 ml.	1%-2%
Mandibular	2-3 ml.	2%
Maxillary	2-3 ml.	2%
Infra-orbital	0.5-1 ml.	2%
Cervical	3-4 ml. (for each segment)	1%-2%
Brachial plexus	30-40 ml.	2%
Ulnar nerve	3-5 ml.	2%
Paravertebral	3-5 ml.	2%
Intercostal	3 ml.	1%-2%
Sciatic nerve	10-15 ml.	2%
Stellate ganglion	5-10 ml.	1%-2%
Lumbar sympathetic (1 needle technic)	15-20 ml.	1%-2%
Interdigital	3-4 ml. (without epinephrine)	1%-2%

Fractional doses, up to 300 to 600 mg., may be given at 50 minute intervals.

2. CAUDAL AND EPIDURAL BLOCK (NESACAINE-CE)

For *caudal anesthesia* the initial dose is 15 to 25 ml. of a 2% or 3% solution. Repeated doses may be given at 40 to 60 minute intervals.

For *epidural anesthesia* in the lumbar and sacral regions 2.0 to 2.5 ml. per segment of a 2% or 3% solution can be used. The usual total volume of Nesacaine-CE is from 15 to 25 ml. Repeated doses 2 to 6 ml. less than the original dose may be given at 40 to 50 minute intervals.

HOW SUPPLIED

Nesacaine is supplied as follows:

1% solution (10 mg/ml.) in 30 ml. multiple-dose vials, 12 vials per carton.

2% solution (20 mg/ml.) in 30 ml. multiple-dose vials, 12 vials per carton.

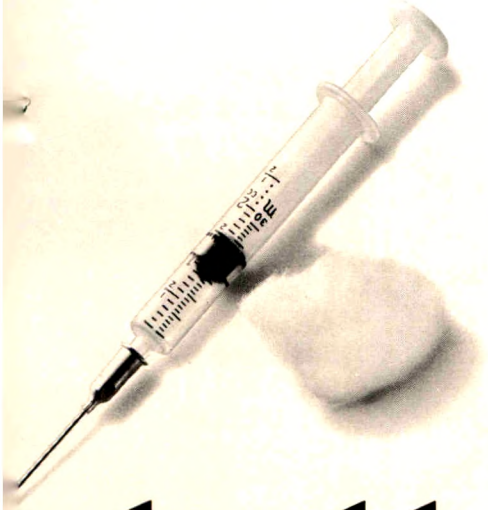
Nesacaine-CE is supplied as follows:

2% solution (20 mg/ml.) in 30 ml. single-dose vials, 12 vials per carton.

3% solution (30 mg/ml.) in 30 ml. single-dose vials, 12 vials per carton.

PENNWALT

Pennwalt Prescription Products
Pharmaceutical Division
Pennwalt Corporation
Rochester, New York 14603



A local anesthetic should meet your needs...

Rapid Onset of Action. Saves doctor, nurse and patient time.

Effective Anesthesia. Nesacaine (Chloroprocaine Hydrochloride) offers 80% to 90% pain-free procedures at recommended doses.

Exceptional Safety. Less potential for postoperative complications. Nesacaine is rapidly hydrolized in plasma, whereas lidocaine and other amide-type local anesthetics are metabolized in the liver. With Nesacaine, therefore, there is minimal potential risk of systemic toxicity, accumulation of metabolites, stimulation of CNS or cardiovascular effects.

Excellent Penetration. Chloroprocaine's lipid solubility and ionization characteristics impart it with excellent penetration.

Minimal Irritation at Injection Site. Few patient complaints about procedural pain, little soreness and inflammation after procedure.

Rapid and Complete Wear-Off. No residual numbness, patient back to normal faster.

See opposite page for brief prescribing information.

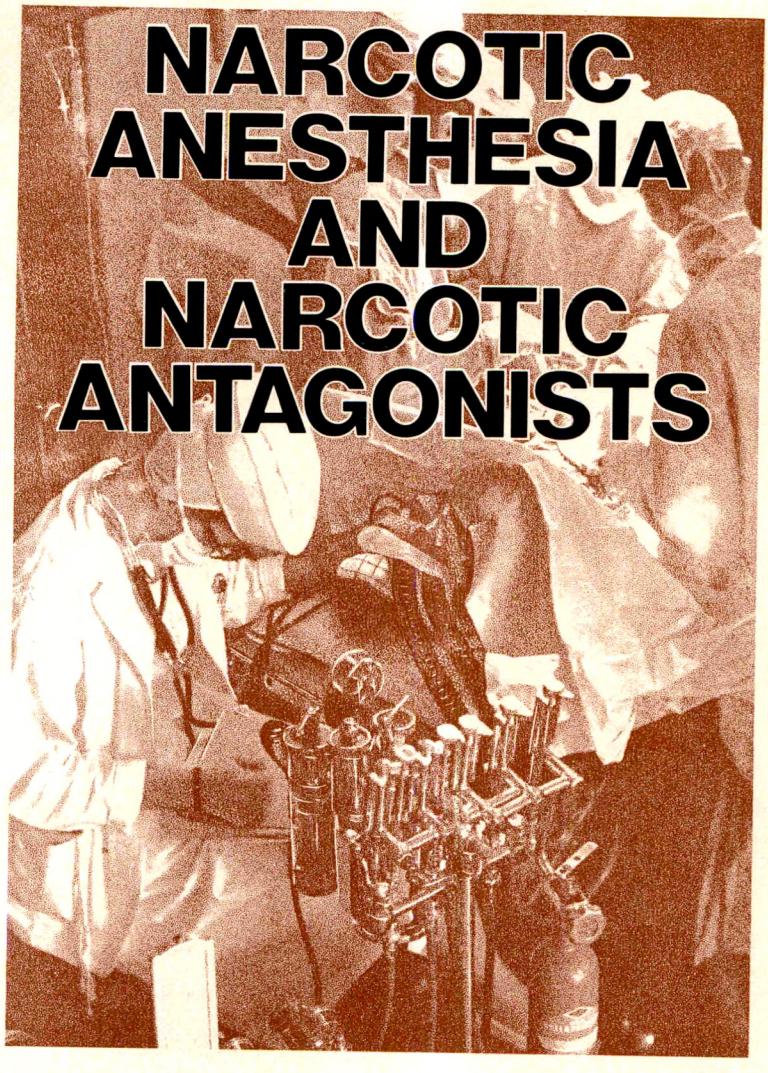
Nesacaine®
(Chloroprocaine Hydrochloride)
It meets your needs.



NARCOTIC ANESTHESIA

- Despite many advantages, the use of opioids to supplement nitrous oxide anesthesia may be associated with significant postoperative depression.

NARCAN® (naloxone HCl)

- Narcan® in sufficient doses wil antagonize opioid effects, including all degrees of respiratory depression and analgesia.
- The degree of narcotic antagonism exhibited by NARCAN® is dose dependent

A recent study of surgical patients receiving narcotic-nitrous oxide anesthesia was undertaken to determine whether careful titration of naloxone would reverse post-operative narcotic depressior and maintain a subjective level of analgesia.[1]

THE OBJECTIVES:

- Restore consciousness
- Reverse narcotic-induced respiratory depression as evidenced by $PaCO_2$
- Maintain *subjective* analgesia

THE METHOD:

- 12 unpremedicated patients received INNOVAR® (fentanyl/droperidol) 5-10 ml I.V. followed by thiopental for induction. Anesthesia was maintained with N_2O-O_2. Increments of 0.1 mg *fentanyl* were given I.V. every 10 minutes during surgery.

Following the procedure, naloxone (0.1 mg/ml) was given in 0.1 mg I.V. increments at 1 minute intervals until the patient was awake, lucid and had adequate tidal and minute volumes. Additional naloxone

1. Heisterkamp DV, Cohen PJ: *Anesth Analg* (Cleve) 53:12-18, Jan-Feb 1974.

NARCAN® is an Endo registered U.S. trademark; U.S. Pat. 3,254,088

was given I.V. as needed in the first 6 patients; a second group of 6 patients received supplemental naloxone I.M. 30 minutes after the initial I.V. dose.

11 patients received 10 mg *morphine* I.M., as well as secobarbital and atropine, 1½ hours preoperatively. Anesthesia was induced by 30 mg morphine given slowly I.V. followed by thiopental and was maintained by N_2O-O_2. Additional morphine was given in divided increments to total 1 mg/kg in the first hour. Further morphine was given as needed. For initial narcotic reversal, naloxone was given as above except at 2 minute intervals. Supplemental naloxone was given I.M. 30 minutes later.

THE RESULTS (fentanyl group):

- When fentanyl was used as the sole narcotic supplement during anesthesia, an I.M. dose of naloxone equal to half the I.V. reversal dose and given ½ hour later provided adequate narcotic reversal.

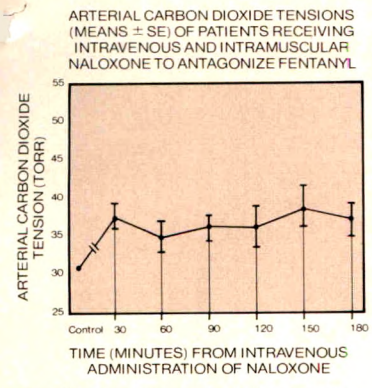


Fig. 1. Control and postoperative $PaCO_2$ in 6 patients receiving I.V. and I.M. naloxone following fentanyl.

THE RESULTS (morphine group):

- "After other narcotics, such as morphine, an I.M. dose of naloxone equal to the I.V. dose appears appropriate."

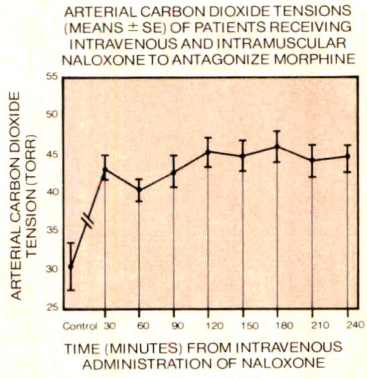

Fig. 2. Control and postoperative $PaCO_2$ in 11 patients receiving I.V. and I.M. naloxone following morphine.

THE CONCLUSIONS:

- "Naloxone provides fast, potent, and reliable antagonism to narcotic-induced respiratory depression."
- "By careful titration, this antagonism can be achieved while acceptable analgesia is maintained."
- "Both morphine and fentanyl groups had adequate analgesia, with only 2 patients [of total 21] requiring pain medication in the recovery room."

- **reverses all degrees of narcotic-induced respiratory depression**
- **does not cause narcotic-like effects**
- **does not augment non-narcotic depression**
- **acts rapidly—generally within 2 minutes following I.V. use and slightly less rapidly when given I.M.**
- **does not lead to tolerance**
- **does not produce psychotomimetic effects or pupillary constriction**
- **can be repeated if initial dose doesn't produce desired degree of narcotic reversal and improvement in respiratory function**
- **following satisfactory response patient should be observed closely and given repeat doses, if necessary, since the duration of action of some narcotics may exceed that of NARCAN®**

Please see next page for complete prescribing information.

DUPONT

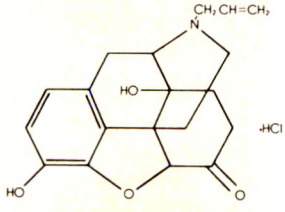
•restored consciousness
•reversed narcotic-induced respiratory depression
•maintained subjective analgesia

NARCAN®
(naloxone HCl)

can reverse narcotic-induced respiratory depression while maintaining subjective analgesia

NARCAN® (naloxone HCl)

DESCRIPTION NARCAN® (naloxone hydrochloride), a narcotic antagonist, is a synthetic congener of oxymorphone. In structure it differs from oxymorphone in that the methyl group on the nitrogen atom is replaced by an allyl group.



NALOXONE HYDROCHLORIDE
(N-allyl-nor-oxymorphone HCl)

Naloxone hydrochloride occurs as slightly off-white crystals, and is soluble in water, slightly soluble in alcohol and practically insoluble in ether.

NARCAN® (naloxone hydrochloride) Injection is available in two concentrations, 0.02 mg and 0.4 mg of naloxone hydrochloride per ml. Each ml of either strength contains 8.6 mg of sodium chloride; and 2.0 mg of methylparaben and propylparaben as preservatives in a ratio of 9 to 1. pH is adjusted with hydrochloric acid.

ACTIONS NARCAN® (naloxone hydrochloride) is an essentially pure narcotic antagonist, i.e., it does not possess the "agonistic" or morphine-like properties characteristic of other narcotic antagonists; NARCAN® (naloxone hydrochloride) does not produce respiratory depression, psychotomimetic effects or pupillary constriction. In the absence of narcotics or agonistic effects of other narcotic antagonists it exhibits essentially no pharmacologic activity.

In the presence of physical dependence on narcotics NARCAN® (naloxone hydrochloride) will produce withdrawal symptoms; it has not been shown to produce tolerance nor to cause physical or psychological dependence.

When NARCAN® (naloxone hydrochloride) is administered intravenously the onset of action is generally apparent within two minutes; the onset of action is only slightly less rapid when it is administered subcutaneously or intramuscularly. The duration of action is dependent upon the dose and route of administration of NARCAN® (naloxone hydrochloride). Intramuscular administration produces a more prolonged effect than intravenous administration. The requirement for repeat doses of NARCAN® (naloxone hydrochloride), however, will also be dependent upon the amount, type and route of administration of the narcotic being antagonized.

INDICATIONS NARCAN® (naloxone hydrochloride) is indicated for the complete or partial reversal of narcotic depression, including respiratory depression, induced by natural and synthetic narcotics, propoxyphene and the narcotic-antagonist analgesic pentazocine.
NARCAN® (naloxone hydrochloride) is also indicated for the diagnosis of suspected acute opiate overdosage.

CONTRAINDICATIONS NARCAN® (naloxone hydrochloride) is contraindicated in patients known to be hypersensitive to it.

WARNINGS NARCAN® (naloxone hydrochloride) should be administered cautiously to persons including newborns of mothers who are known or suspected to be physically dependent on opioids. In such cases an abrupt and complete reversal of narcotic effects may precipitate an acute abstinence syndrome.

The patient who has satisfactorily responded to NARCAN® (naloxone hydrochloride) should be kept under continued surveillance and repeated doses of NARCAN® (naloxone hydrochloride) should be administered, as necessary, since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydrochloride).

NARCAN® (naloxone hydrochloride) is not effective against respiratory depression due to non-opioid drugs.

Usage in Pregnancy Safe use of NARCAN® (naloxone hydrochloride) during pregnancy (other than labor) has not been established. Animal reproduction studies have not demonstrated teratogenic or other embryotoxic effects (See ANIMAL PHARMACOLOGY AND TOXICOLOGY). However, NARCAN® (naloxone hydrochloride) should be administered to pregnant patients only when, in the judgment of the physician, the potential benefits outweigh the possible hazards.

PRECAUTIONS In addition to NARCAN® (naloxone hydrochloride), other resuscitative measures such as maintenance of a free airway, artificial ventilation, cardiac massage, and vasopressor agents should be available and employed when necessary to counteract acute narcotic poisoning.

In an isolated report two patients with pre-existing ventricular irritability requiring lidocaine, and either isoproterenol or epinephrine for hypotension following cardiopulmonary bypass proced developed ventricular tachycardia or fibrillation when given NARCAN® (naloxone hydrochlori I.V. at 9 and 14 hours, respectively, postoperatively for persistent unresponsiveness. Althoug direct cause and effect relationship has not been established, NARCAN® (naloxone hydrochl should be used with caution in patients with cardiac irritability.

ADVERSE REACTIONS In rare instances nausea and vomiting have been reported in postoper patients receiving NARCAN® (naloxone hydrochloride) in doses higher than that recommende cause and effect relationship has not been established.

DOSAGE AND ADMINISTRATION NARCAN® (naloxone hydrochloride) may be administered intra ously, intramuscularly, or subcutaneously. The most rapid onset of action is achieved by intravenous administration and it is recommended in emergency situations.

Since the duration of action of some narcotics may exceed that of NARCAN® (naloxone hydroc ride) the patient should be kept under continued surveillance and repeated doses of NARCAN (naloxone hydrochloride) should be administered, as necessary.

USAGE IN ADULTS Narcotic Overdose—Known or Suspected The usual initial adult dose is (mg (1 ml) NARCAN® (naloxone hydrochloride) administered I.V., I.M. or S.C. If the desired deg of counteraction and improvement in respiratory function is not obtained immediately followi I.V. administration, it may be repeated intravenously at 2 to 3 minute intervals. Failure to obt significant improvement after 2 or 3 doses suggests that the condition may be due partly or c pletely to other disease processes or non-opioid drugs.

Post Operative Narcotic Depression For the partial reversal of narcotic depression following use of narcotics during surgery, smaller doses of NARCAN® (naloxone hydrochloride) are usua sufficient. The dose of NARCAN® (naloxone hydrochloride) should be titrated according to the patient's response. Excessive dosage of NARCAN® (naloxone hydrochloride) may result in sigr cant reversal of analgesia and increase in blood pressure. Similarly, too rapid reversal may induce nausea, vomiting, sweating or tachycardia.

For the initial reversal of respiratory depression, NARCAN® (naloxone hydrochloride) should be injected in increments of 0.1 to 0.2 mg intravenously at two to three minute intervals to the desired degree of reversal i.e., adequate ventilation and alertness without significant pain or comfort.

Repeat doses of NARCAN® (naloxone hydrochloride) may be required within one to two hour in vals depending upon the amount, type (i.e., short or long acting) and time interval since last administration of narcotic. Supplemental intramuscular doses have been shown to produce a longer lasting effect.

USAGE IN CHILDREN Narcotic Overdose—Known or Suspected The usual initial child dose i 0.01 mg/kg body weight given I.V., I.M. or S.C. This dose may be repeated in accordance with adult administration guideline. If necessary, NARCAN® (naloxone hydrochloride) can be dilute with sterile water for injection.

USAGE IN NEONATES Narcotic-induced depression The usual initial dose is 0.01 mg/kg body weight administered I.V., I.M. or S.C. This dose may be repeated in accordance with adult administration guidelines.

HOW SUPPLIED 0.4 mg/ml of NARCAN® (naloxone hydrochloride) for intravenous, intramuscu and subcutaneous administration.

Available in 1 ml ampuls in boxes of 10 and 100.

0.02 mg/ml of NARCAN® (naloxone hydrochloride) NEONATAL INJECTION for intravenous, intramuscular and subcutaneous administration.

Available in 2 ml ampuls in boxes of 10 and 100 ampuls.

ANIMAL PHARMACOLOGY AND TOXICOLOGY In the mouse and rat the intravenous LD_{50} is 150 mg/kg and 109 ±4 mg/kg respectively. In acute subcutaneous toxicity studies in newborn rat the LD_{50} (95% CL) is 260 (228-296) mg/kg. Subcutaneous injection of 100 mg/kg/day in rats 3 weeks produced only transient salivation and partial ptosis following injections; no toxic effe were seen at 10 mg/kg/day for 3 weeks.

Reproductive studies including fertility, general reproductive performance, embryotoxicity, tera togenicity, and lactation did not show any abnormality in mice and rats at 10 mg/kg/day.

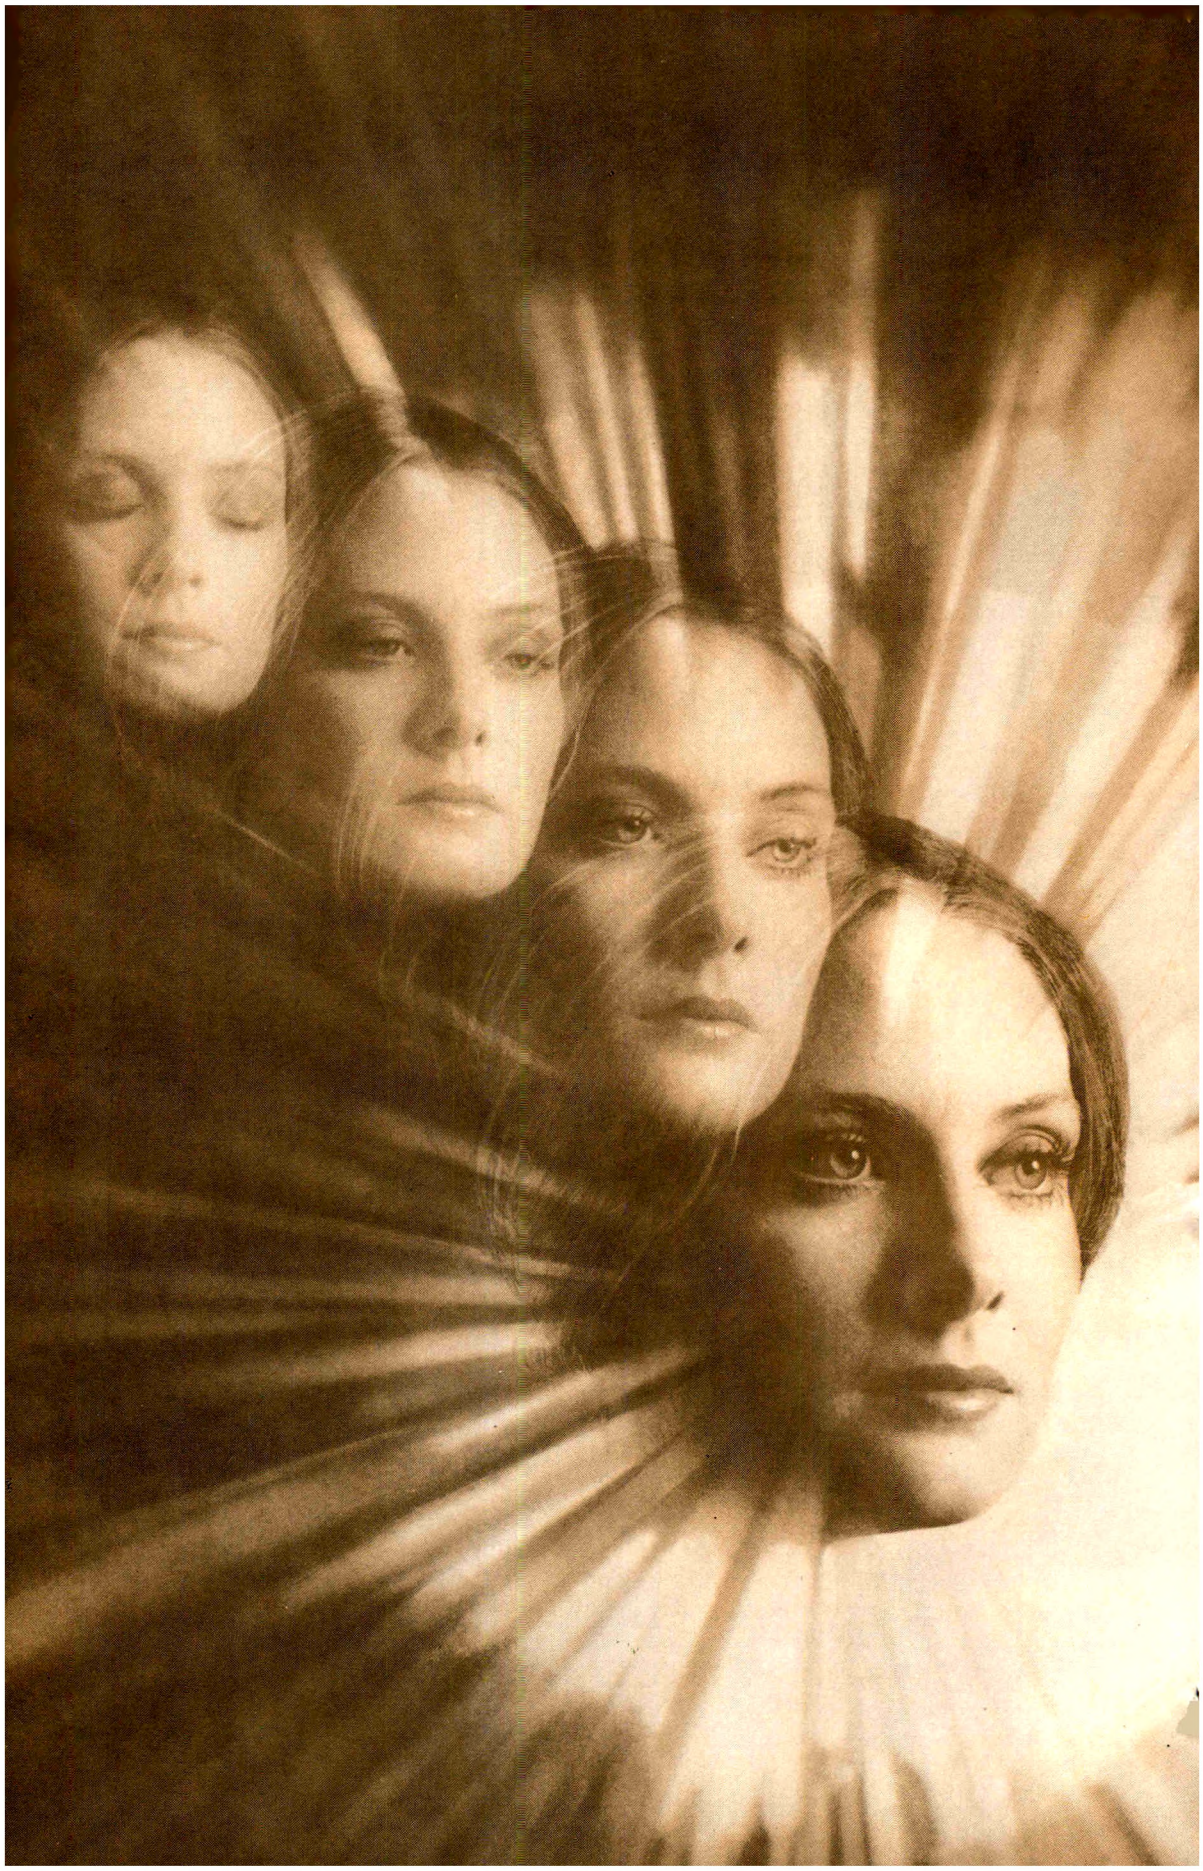
Henry Knowles Beecher, MD, has been named the first recipient of an award for contributions to ethics and the life sciences established in his name by the Institute of Society, Ethics and the Life Sciences. Dr. Beecher is Henry Isaiah Dorr Professor of Research in Anaesthesia Emeritus at Harvard Medical School and a founding Fellow of the Institute.

The Henry Knowles Beecher Award for Contributions to Ethics and the Life Sciences will honor those whose careers have combined devotion to the highest ideals of scholarship and research with a dedication to ethical inquiry. It will be given at least once every five years but not more than once every two years.



A "quick recovery" anesthetic for short surgical procedures

Ethrane® (enflurane) fulfills your anesthetic requirements for short surgical procedures.

Fast Induction, Rapid Recovery. The low blood/gas partition coefficient of ETHRANE (1.91 at 37°C) assures rapid patient induction with minimal excitation. Its mild, pleasant odor is highly acceptable and ETHRANE does not stimulate increased salivation or affect bronchomotor tone.[1] Pharyngeal and laryngeal reflexes can be quickly and easily obtunded. Following anesthesia, because of its low blood solubility, ETHRANE is promptly eliminated at the lungs, permitting rapid emergence and recovery.[2]

Stable Cardiac Rhythm. Cardiac rhythm usually remains normal during ETHRANE anesthesia and is not altered even with elevations in arterial carbon dioxide.[3] Although nodal or atrial arrhythmias occasionally appear, ventricular extrasystoles are rare. Heart rate is sustained at preanesthetic levels. Bradycardia or tachycardia do not normally occur. Blood pressure tends to be reduced with induction, but this effect is reversed with surgical stimulation.[4]

Excellent Muscle Relaxation. At clinical concentrations, ETHRANE usually provides muscle relaxation sufficient for lower abdominal procedures. In addition, relaxation is often adequate for procedures of the upper abdomen. If greater relaxation is required, its potentiation of nondepolarizing relaxants reduces the dosage of such adjunctive neuromuscular blocking agents.[4]

Few Anesthetic Aftereffects. Following cessation of anesthesia with ETHRANE, recovery is rapid, uneventful, and complete. Postoperative return of adequate pulmonary ventilation is rapid.[1] Nausea, vomiting, and delirium are rare. Usually there is an early return of lucidity, desire for fluids, and generally a feeling of well-being.[1,5]

WARNING: Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. For additional warnings, contraindications, and precautions, see following page.

Films Available for Medical Education. As a service to the anesthesia profession, Ohio Medical Products has available, without charge, motion pictures for use in continuing medical education. Topics include such areas as "Management of Ambulatory Surgical Procedures" and "The Use of ETHRANE." To arrange for a personal or group showing, contact your OHIO Anesthetic Representative, or write to our Communications Department in Madison, Wisconsin.

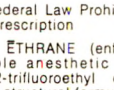
Ethrane® (enflurane) Versatile in concept... Versatile in performance.

CAUTION: Federal Law Prohibits Dispensing without Prescription

Description: ETHRANE (enflurane) is a nonflammable anesthetic agent. It is 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether, and its structural formula is:



Some physical constants of the compound are:

Molecular weight	184.5
Boiling point 760 mm Hg.	56.5°C
Refractive index n_D^{20}	1.3026-1.3030
Specific gravity 25°/25°C	1.517
Vapor pressure in mm Hg.**	20°C 174.5 25°C 217.7 36°C 345.2

**Equation for calculation of enflurane vapor pressures:

$$\log_{10} P = A + \frac{B}{T}$$

A = 7.967
B = −1678.4
T = °C + 273.16 (Kelvin)

Partition coefficients @ 37°C	
Water-gas	0.82
Blood-gas	1.91
Oil-gas	98.5
Partition coefficients @ 25°C— rubber and plastic	
Conductive rubber	74.0
Butyl rubber	90.0
Polyvinylchloride	120.0
Polyethylene	≈2.0
Polyurethane	≈1.5
Polyolefin	≈1.2
Butyl acetate	≈3.0
Solubility of enflurane in H_2O at 22°C	0.275%
Solubility of H_2O in enflurane	0.13%
Purity by gas chromatography	>99.9%
Flammability in air	None
Flammability in oxygen (Entire concentration range to saturation at 71 and 113°F and 743 mm Hg. pressure.)	None
M.A.C. (Minimum alveolar concentration)	
Man with pure oxygen	1.68
Man with 70% nitrous oxide	0.56 (est.)

ETHRANE is a clear, colorless, stable liquid without added chemical stabilizers. ETHRANE has a mild, sweet odor. Storage of samples in indirect sunlight in clear, colorless glass for a five year period, as well as direct exposure for 30 hours to a 2 amp, 115 V., 60 cycle long wave U.V. light, produced no changes in composition detectable by gas chromatography. ETHRANE in one normal sodium methoxide-methanol solution, a strong base, for over six months consumed none of the alkali, indicative of strong base stability. ETHRANE does not decompose in contact with soda lime. ETHRANE does not attack aluminum, tin, brass, iron or copper.

Actions: ETHRANE (enflurane) is an inhalation anesthetic. Induction and recovery from anesthesia with ETHRANE are rapid. ETHRANE does not appear to stimulate excess salivation or tracheobronchial secretions, or affect bronchomotor tone. Pharyngeal and laryngeal reflexes are readily obtunded. The level of anesthesia changes rapidly with ETHRANE. ETHRANE reduces ventilation as depth of anesthesia increases. ETHRANE provokes a sigh response reminiscent of that seen with diethyl ether.

There is a decrease in blood pressure with induction of anesthesia, followed by a return to near normal with surgical stimulation. Progressive increases in depth of anesthesia produce corresponding increases in hypotension. Heart rate remains relatively constant without significant bradycardia. Electrocardiographic monitoring or recordings indicate that cardiac rhythm remains stable. Elevation of the carbon dioxide level in arterial blood does not alter cardiac rhythm. ETHRANE sensitizes the myocardial conduction system to epinephrine in dog and can produce serious arrhythmias. Comparable information in man is not available.

Muscle relaxation is adequate for intra-abdominal operation at normal levels of anesthesia. Should greater relaxation be necessary, minimal doses of muscle relaxants may be used. All commonly used muscle relaxants are compatible with ETHRANE. **The nondepolarizing muscle relaxants are markedly potentiated.** Neostigmine does not reverse the direct effect of ETHRANE.

Biotransformation of ETHRANE (enflurane) in man results in low levels of serum fluoride ions averaging 15 mM/L. These levels are well below the 50 mM/L seen to produce renal damage in normal subjects; however, it is possible that these levels could result in damage in patients with severely impaired renal function or those undergoing renal transplantation.

Indications: ETHRANE (enflurane) may be used for induction and maintenance of general anesthesia. Adequate data have not been developed to establish its application in obstetrical anesthesia.

Contraindications: Seizure disorders (see WARNINGS).

Known sensitivity to ETHRANE (enflurane) or other halogenated anesthetics.

Warnings: Increasing depth of anesthesia with ETHRANE (enflurane) produces a change in the electroencephalogram characterized by high voltage, fast frequency, progressing through spike-dome complexes alternating with periods of electrical silence to frank seizure activity. The latter may or may not be associated with motor movement. Motor activity, when encountered, generally consists of twitching or "jerks" of various muscle groups; it is self-limiting and can be terminated by lowering the anesthetic concentration. This electroencephalographic pattern associated with deep anesthesia is exacerbated by hyperventilation producing low arterial carbon dioxide tension. The pattern serves as a warning that depth of anesthesia is excessive. Cerebral blood flow and metabolism studies in normal volunteers during seizure patterns show no evidence of cerebral hypoxia, and recovery appears to be uncomplicated.

Since levels of anesthesia may be altered easily and rapidly, only calibrated vaporizers which measure output with reasonable accuracy should be used. Hypotension and respiratory exchange can serve as a guide to anesthesia depth. With deep levels of anesthesia, more marked hypotension and respiratory depression are encountered.

The action of nondepolarizing relaxants is augmented by ETHRANE. Less than the usual amounts of these drugs should be used. The time for recovery from the myoneural effect of these relaxants is greater in the presence of ETHRANE than for other commonly used anesthetics.

The safety of the use of epinephrine topically and subcutaneously has not been established in man.

Usage in Pregnancy: Safety in pregnancy has not been established. Reproduction studies have been performed in rats and rabbits, and there is no evidence of harm to the animal fetus. The relevance of these studies to the human is not known. Since there is no adequate experience in pregnant women who have received the drug, safety in pregnancy has not been established.

Precautions: Bromsulfalein (BSP) retention is mildly elevated postoperatively in some cases. There is some elevation of glucose and white blood count intraoperatively. Glucose elevation should be considered in diabetic patients. ETHRANE (enflurane) should be used with caution in patients who by virtue of medical or drug history could be considered more susceptible to cortical stimulation produced by this drug. As with other general anesthetics and some muscle relaxants, hyperpyrexia has been observed with the use of ETHRANE.

Adverse reactions: 1. Motor activity exemplified by movement of various muscle groups and/or seizures may be encountered with deep levels of ETHRANE (enflurane) anesthesia. 2. Hypotension and respiratory depression have been reported. 3. Arrhythmias, shivering, nausea, and vomiting have been reported. 4. Elevation of the white blood count has been observed. It has not been determined whether this is related to ETHRANE or to surgical stress.

Dosage and administration: The concentration of ETHRANE (enflurane) being delivered during anesthesia from a vaporizer should be known. This may be accomplished by using:

a) vaporizers calibrated specifically for ETHRANE;
b) vaporizers from which delivered flows can easily and readily be calculated.

Maintenance concentration should not exceed 3%. Premedication should be selected according to the need of the individual patient, taking into account that secretions are weakly stimulated by ETHRANE and the heart rate remains constant. The use of anticholinergic drugs is a matter of choice.

Induction: Induction may be achieved using ETHRANE alone with oxygen or in combination with oxygen-nitrous oxide mixtures. Under these conditions some excitement may be encountered. If excitement is to be avoided, a hypnotic dose of a short-acting barbiturate should be used to induce unconsciousness, followed by the ETHRANE mixture. In general, inspired concentrations of 3.5-4.5% ETHRANE produce surgical anesthesia in 7-10 minutes.

Maintenance: Surgical levels of anesthesia may be attained with 1.5-3.0% concentration. If added relaxation is required, supplemental doses of muscle relaxants may be used. Ventilation to maintain the tension of carbon dioxide in arterial blood in the 35-45 mm range is preferred to hyper- or hypoventilation in order to minimize possible CNS excitation.

The level of blood pressure during maintenance is an inverse function of ETHRANE concentration in the absence of other complicating problems. Excessive decreases (unless related to hypovolemia) may be due to depth of anesthesia and in such instances should be corrected by lightening the level of anesthesia.

Overdosage: In the event of overdosage, or what may appear to be overdosage, the following action should be taken:

Stop drug administration; establish that the airway is clear and initiate assisted or controlled ventilation with pure oxygen as circumstances dictate.

Administration equipment: ETHRANE (enflurane) may be administered from a flow-through type vaporizer manufactured and specifically calibrated for ETHRANE. Vaporizers which deliver saturated vapor at reasonable flows but are not specifically calibrated for ETHRANE may be used.

ETHRANE contains no stabilizer. Nothing is present in the agent to alter calibration or affect the operation characteristics of the vaporizer.

Packaging: ETHRANE (enflurane) is packaged in 125 and 250 ml. amber bottles. No additives or stabilizers are present.

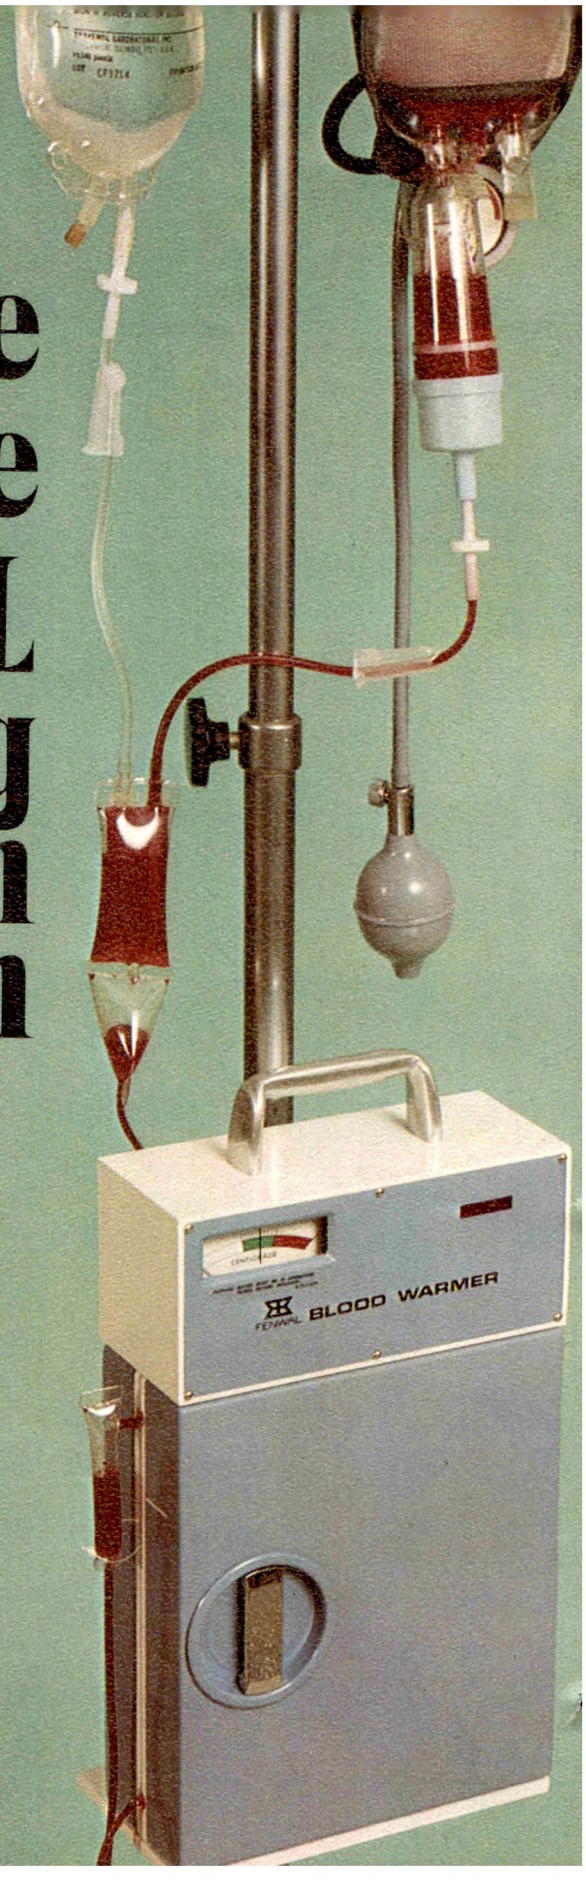
patients

The complete FENWAL operating room system



The Fenwal Dry Heat Blood Warmer is designed for use during single or multiple transfusions when precise regulation of blood temperature and flow rate is indicated. It utilizes a disposable plastic blood-warming pathway.

Fenwal Recipient Sets are available to accommodate your infusion requirements. The Single Lead Set is to be used for the intravenous administration of one unit of whole blood, red cells or plasma. The "Y" Recipient Set is designed to permit dual hookups for simultaneous administration of blood and/or solutions. The Triple Lead Set may be employed in multiple infusion procedures, i.e., blood, solutions, blood components and medication.

The Fenwal Microaggregate Blood Filter is designed to remove microaggregates down to 20 microns in size during intravenous administration of stored whole blood or red cells.

Fenwal Pressure Infusors provide an efficient non-air-dependent method for the rapid infusion of whole blood or red cells.

The Fenwal TYPENEX™ Blood Recipient Identification System ties together the identity of the transfusion candidate, his cross-match request form, blood sample and up to 10 cross-matched units of blood.

The Fenwal Venous Pressure Manometer Set is a disposable, preassembled unit that permits continuous monitoring of the patient's venous pressure while performing one simple hookup.

The Fenwal Platelet Recipient Set is designed specifically for the infusion of fresh blood and pool platelet concentrates.

Our best to you

Fenwal Laboratories has long been identified with innovation in modern blood handling systems. Our knowledge and experience in developing and providing sophisticated blood processing systems have earned a reputation for excellence. Thoroughly researched and tested to meet the demands of the medical profession, you can expect the same quality in Fenwal operating room devices that helped achieve our recognition with the nation's blood banks.

The Fenwal Specialist in your hospital can provide you and the other members of the operating team with completely detailed information on all of our products. Intensive training makes him fully qualified to answer your most involved questions regarding up-to-date blood transfusion procedure. Be sure to see your Fenwal Specialist the next time he visits your department.

INJECTION, equivalent to 10 mg metaraminol per ml

Aramine® (Metaraminol Bitartrate | MSD)

a vasopressor with positive inotropic effect

Indications: Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
Effective: ARAMINE is indicated for prevention and treatment of the acute hypotensive state occurring with spinal anesthesia. Adjunctive treatment of hypotension due to hemorrhage; reactions to medications; surgical complications; and shock associated with brain damage due to trauma or tumor.
"Probably" effective: It may also be useful as an adjunct in the treatment of hypotension due to cardiogenic shock or septicemia.
Final classification of the less-than-effective indications requires further investigation.

Contraindications: Use should be avoided with cyclopropane or halothane anesthesia, unless clinical circumstances demand such use.

Precautions: Use with caution to avoid excessive blood pressure response. Rapidly induced hypertensive responses have been reported to cause acute pulmonary edema, arrhythmias, and cardiac arrest. Use with caution in digitalized patients, since the combination of digitalis and sympathomimetic amines is capable of causing ectopic arrhythmic activity. Treat cirrhotic patients cautiously; if diuresis ensues, restore electrolytes. Fatal ventricular arrhythmia has been reported in one patient with Laennec's cirrhosis. In several instances, ventricular extrasystoles that appeared during infusion have subsided promptly on reduction of infusion rate. Since metaraminol has prolonged duration of action, a cumulative effect is possible, leading to prolonged elevation of blood pressure even with discontinuation of therapy. Monoamine oxidase inhibitors have been reported to potentiate action of sympathomimetic amines.
When vasopressor amines are used for long periods, resulting vasoconstriction may prevent adequate expansion of circulating volume and may cause perpetuation of the shock state. Plasma volume may be reduced in all types of shock, and measurement of central venous pressure is the most useful means of assessing the adequacy of the circulating blood volume; blood or plasma volume expanders should be employed for hypotension or shock due mainly to decreased circulating volume. Because of its vasoconstrictor effect, metaraminol should be used with caution in heart or thyroid disease, hypertension, or diabetes. Sympathomimetic amines may provoke relapse in patients with history of malaria.

Adverse Reactions: Sinus or ventricular tachycardia, or other arrhythmias, especially in patients with myocardial infarction. Abscess formation, tissue necrosis, or sloughing may rarely follow use. In choosing the site of injection, it is important to avoid those areas recognized as *not* suitable for use of any pressor agent, and to discontinue infusion immediately if infiltration or thrombosis occurs. The larger veins of the antecubital fossa or the thigh are preferred to veins in the dorsum of the hand or ankle veins, particularly in patients with peripheral vascular disease, diabetes mellitus, Buerger's disease, or conditions with coexistent hypercoagulability.

Note: Response to vasopressors may be poor in patients with coexistent shock and acidosis. Established methods of shock management, such as blood or fluid replacement when indicated, and other measures directed to the specific cause of the shock state also should be used. *Only Sodium Chloride Injection or 5 percent Dextrose Injection should be used as a diluent.*

How Supplied: Injection, in 1-ml ampuls and 10-ml vials, containing per ml: metaraminol bitartrate equivalent to 10.0 mg metaraminol; inactive ingredients: sodium chloride, 4.4 mg; water for injection, q.s. ad 1.0 ml; and 0.15% methylparaben, 0.02% propylparaben, and 0.2% sodium bisulfite added as preservatives.

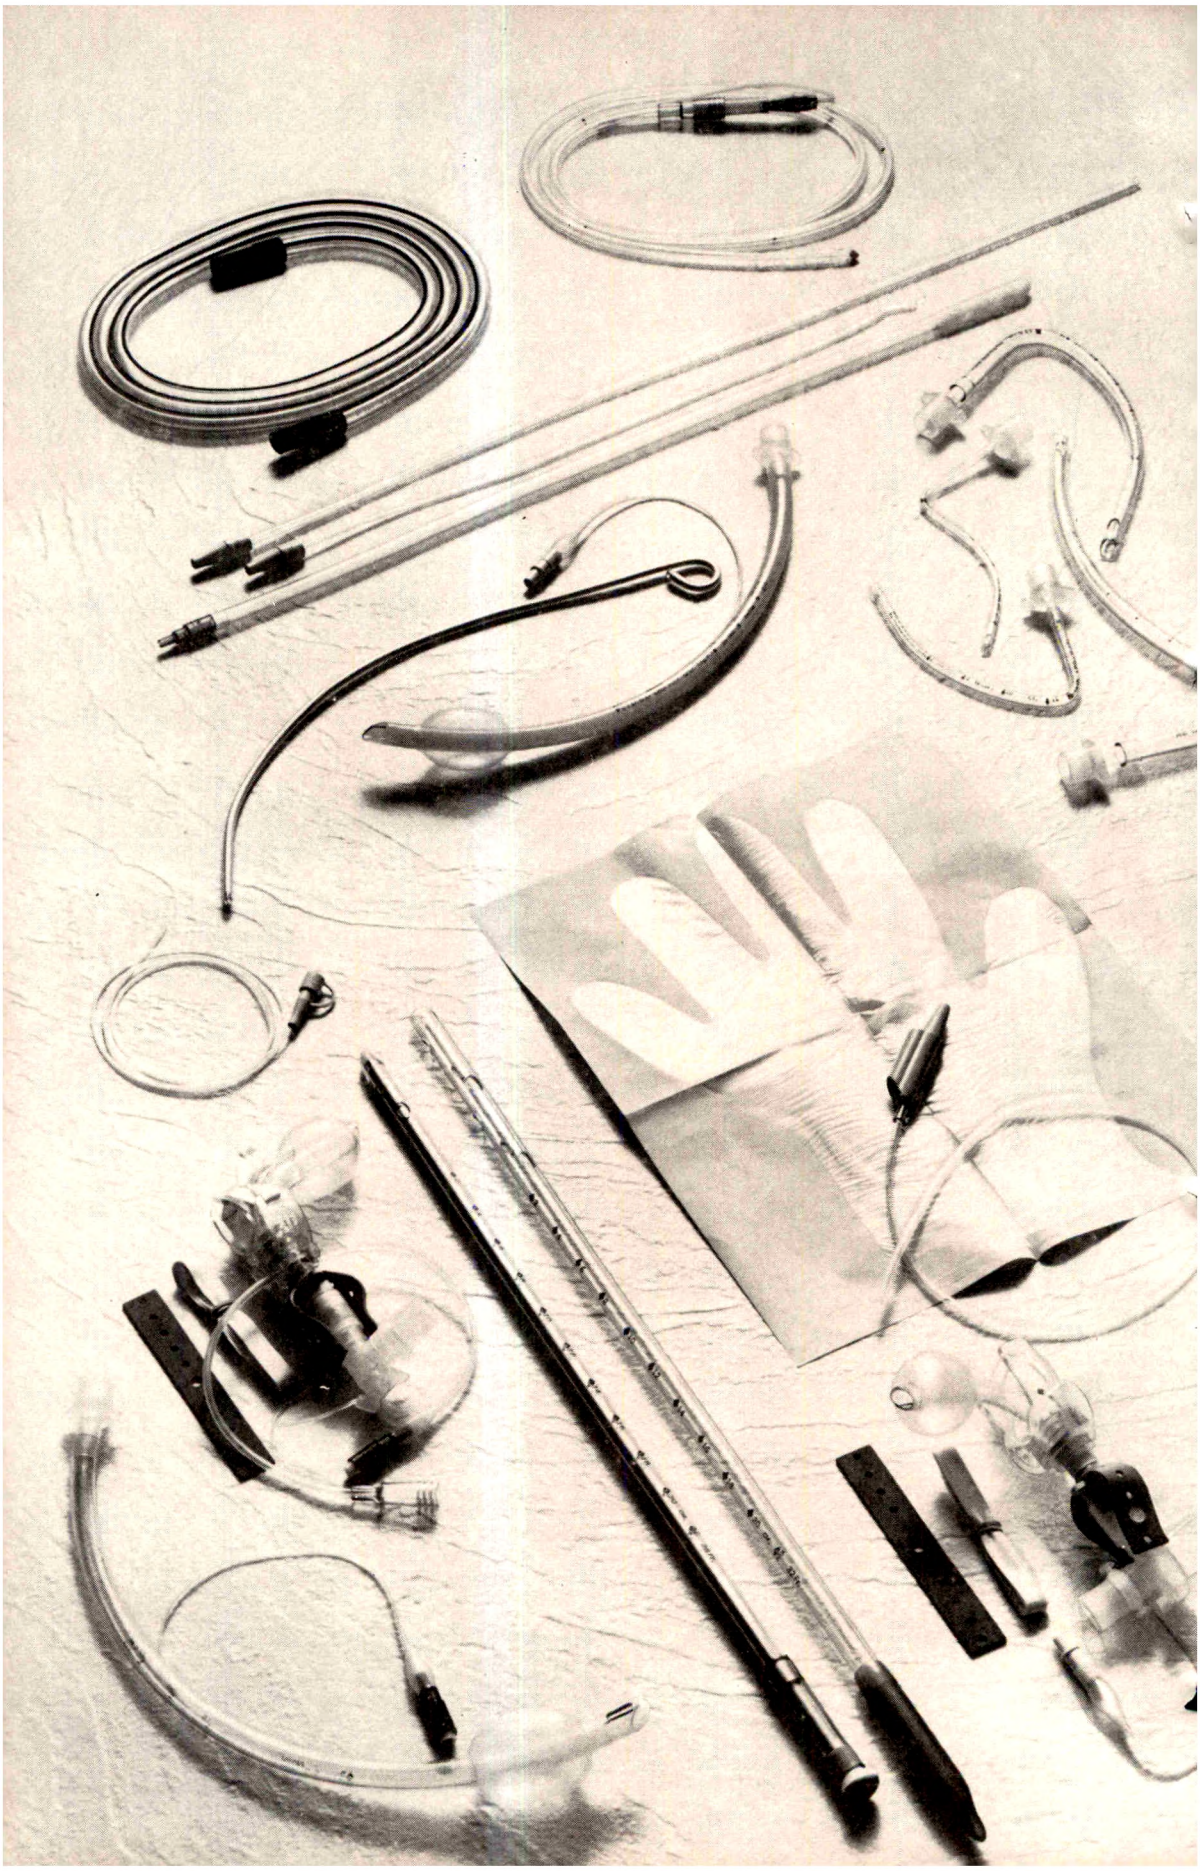
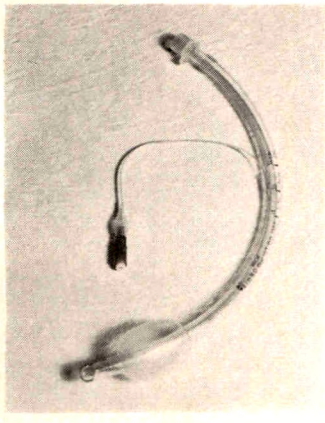
MERCK SHARP & DOHME



National Catheter... we make lifelines.



hi-lo® tracheal tubes*

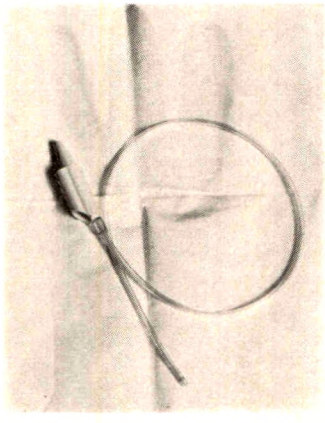
A high volume, low pressure cuffed endotracheal tube that inflates with a minimum of air pressure. Creates a no-leak seal, usually of less than 25 cm. H_2O; avoids trauma to the tracheal wall.

Soft and pliant tubes have a true murphy tip, intubate easily. Water clear, the tube fogs on exhalation, an instant monitor of patient respiratory function. May be used orally or nasally.

Other trademarks of NCC: **holdtite™, vari-form®, ventrol®, suture rib™, versi-cath®, maxi-flex & vac™, RAE™.**

*Covered under one or more of the following patents, U.S. Pat. No's 3,625,793, 3,605,750, 3,508,554, 3,610,242, and patents pending.

†University of Pittsburgh



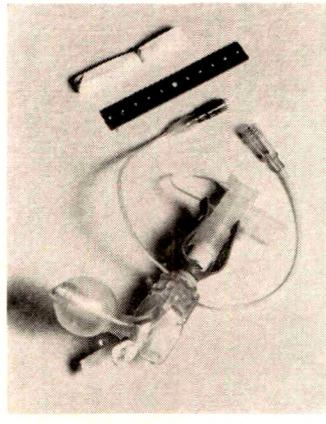
Ncc satin-cath™* & gluv set

This sterile, disposable gluv set has met with overwhelming acceptance.

The GENTLE-FLO® catheter has a SATIN-SLIP SURFACE™ that provides smooth, non-binding insertion into an endotracheal tube.

The paperbacked glove slips on easily, fits either hand and is easily removed when suctioning is complete. The set also contains a waterproof receptacle. Pull the marked tabs and it opens and locks in position, ready to use for the receipt of sterile water. Equipped with VACTROL® connector, catheter suction may be simply regulated from full on to off.

Available with catheters in all popular sizes. Packaged in a sterile peel-back paper pouch—50 sets/box.



pitt*† trach speaking tube

This speaking tube permits tracheostomy patients to converse. The emotional benefits are obvious.

The hi-lo® cuff inflates easily to avoid tracheal damage. This possibility is further removed because the clear tubing permits convenient bronchoscopic observation of the tracheal wall. The auxiliary air supply tube is to be connected to a humidified air oxygen outlet to achieve a speaking air flow.

Equipped with Eross Safety Straps and removable spacers and adjustable collar, the trach tube is adaptable to fit any adult patient. The suction port, which may be locked, allows for suctioning of the patient without removing the respirator and introducing a flexible fiberoptic bronchoscope, thus avoiding delays during this critical period.

Manufactured with the precision medicine must demand.

PRECISE, ECONOMICAL, SAFE...

RALS POWER UNIT

...INSTANT ATOMIZATION FOR FAST TOPICAL ANESTHESIA

Fast, measured topical anesthesia is ready at your finger tips in a Rals Power Unit. Forget about pumping bulbs, uneven atomization, and limited spraying duration. The Rals Power Unit uses a non-toxic propellant, dichlorodifluoromethane (freon) to activate standard DeVilbiss Atomizers No's. 151, 152 and 163. Instantly, a fine mistlike spray is produced. A graduated solution vial is available for measuring the amount of solution administered.

The Rals Power Unit has been proven effective in cocainization prior to endotracheal intubation, endoscopic instrumentation, laryngotracheal insufflation, and in a variety of nose and throat procedures.

Rals Power Unit #168 are supplied six to a box with adaptor top and metal base. Illustration shows #152 atomizer. All styles in stock.

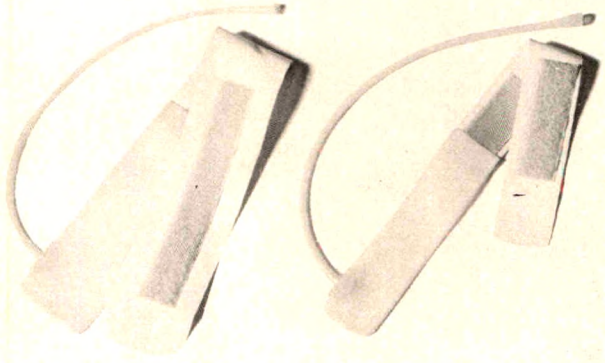
The tender touch



These soft, pliable blood pressure cuffs are ideal for use on newborns and infants. Incorporating a Latex bladder, minimizing any chances for skin irritation, and Silicon wrap-around with 12-inch inflating tube. They are secured by the Velcro hook and pile method, with no eyes to hook nor ends to tuck in. They are instantly peeled apart for easy removal.

Cuffs are available in two sizes:
22080 - 1⅜ x 5" (new born)
22081 - 2¼ x 6" (infant)

For additional information write for brochure number 27.

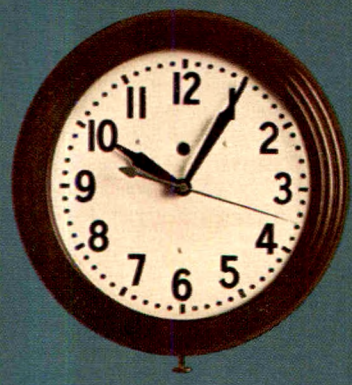
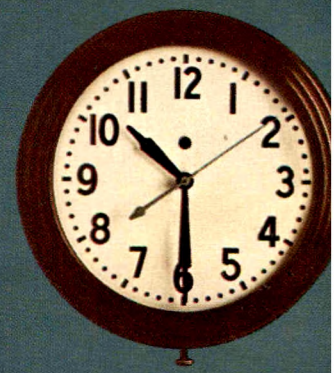
SUBLIMAZE® (fentanyl) has a uniquely short duration of analgesic action—for more precise control and minimal risk of prolonged narcotic effects.

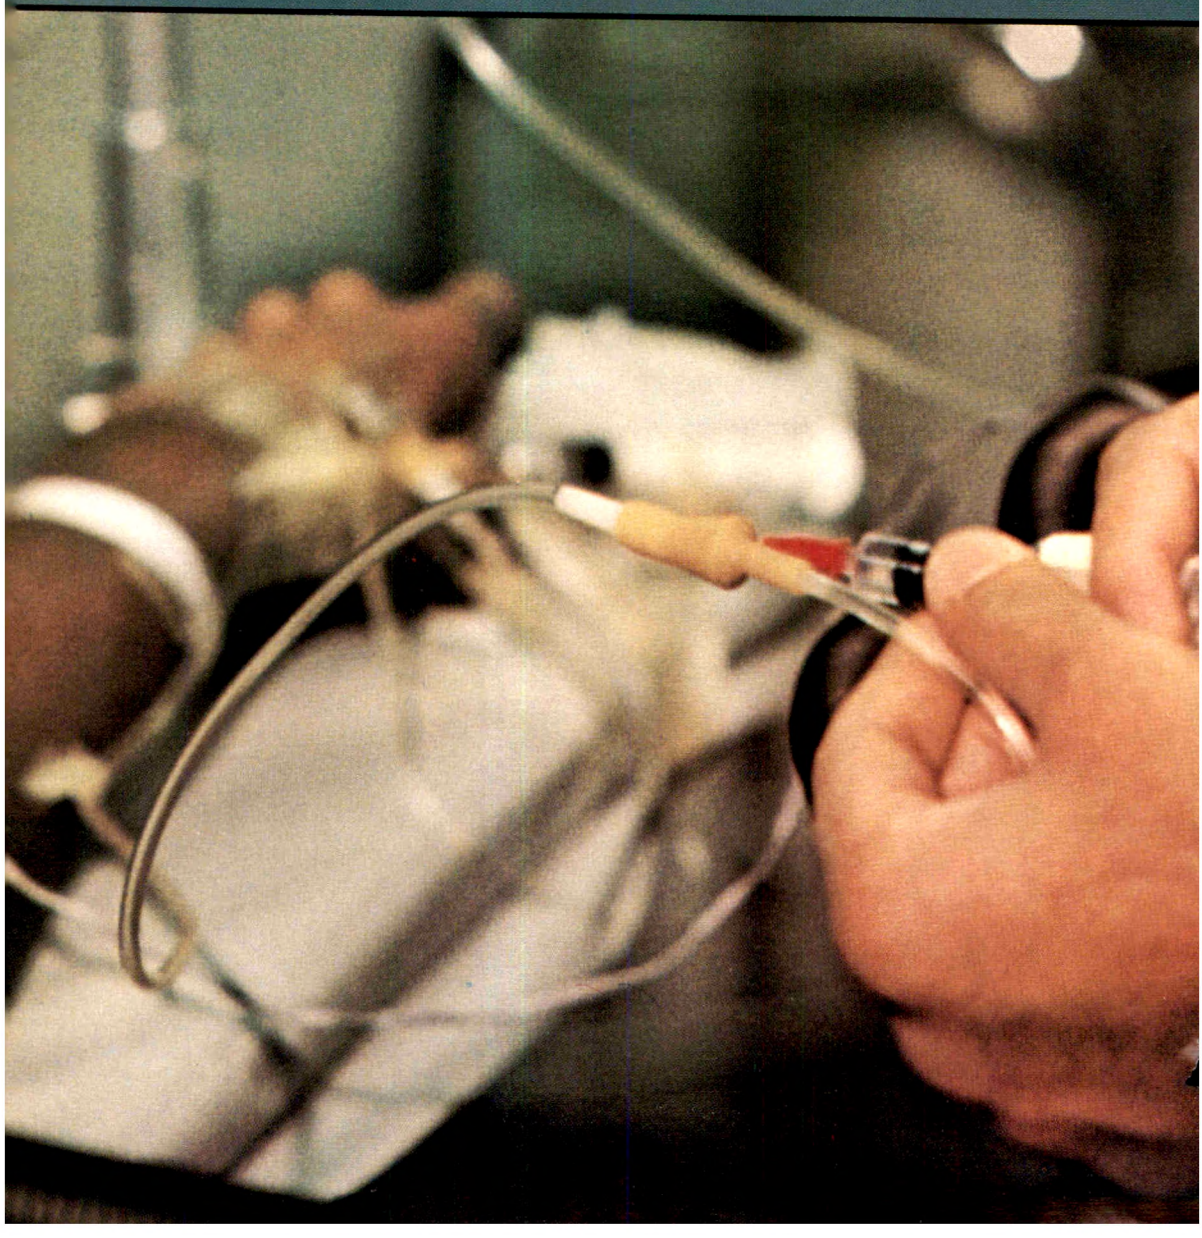


Within 5 minutes I.V., SUBLIMAZE® (fentanyl) reaches its peak analgesic effect.



Within 30 to 60 minutes I.V., the analgesic effect of SUBLIMAZE® (fentanyl) is almost completely dissipated.†

† Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with large doses, multiple doses or use of postoperative narcotic analgesics.



For potent narcotic analgesic action with rapid onset and short duration:

SUBLIMAZE fentanyl provides profound analgesia without hypnosis and with little or no sedation. With this analgesia as a foundation, it is possible to use light general anesthesia in most cases.

SUBLIMAZE fentanyl is particularly suited for maintenance of analgesia after INNOVAR® injection* has been used for induction. It may also be used preoperatively, during surgery with any common general or regional anesthetic agent, and in the immediate postoperative period whenever the need for potent analgesic action arises.

SUBLIMAZE fentanyl is available both alone and as a component of INNOVAR injection.*

*INNOVAR injection is composed of a 50:1 mixture of droperidol 2.5 mg./cc. and fentanyl 0.05 mg./cc., with lactic acid for adjustment of pH to 3.5 ± 0.3.

SUBLIMAZE® (fentanyl) offers:

☐ Almost immediate analgesia—peak effect within 5 minutes I.V., 8 minutes I.M.

☐ Short duration of analgesic action—30 to 60 minutes with a single I.V. dose of up to 0.1 mg. (Respiratory depressant effects may last longer than the analgesia and are increased and prolonged with larger doses, multiple doses or use of postoperative narcotic analgesics.)

☐ No evidence of liver, heart, or kidney toxicity—expecially valuable in poor-risk patients. However, the drug should be administered cautiously in the presence of liver or kidney dysfunction or cardiac arrhythmias, and the dose should be appropriately reduced in poor-risk patients.

☐ Immediate reversibility by narcotic antagonists.

☐ Little or no histamine release—decreasing the risk of cardiovascular instability.

☐ Minimal emetic effect—has been used successfully to prepare nonfasting patients for awake intubation.

☐ Prevention or reversal of emergence delirium and tachypnea.

SUBLIMAZE® (fentanyl) injection

0.05 mg./cc. as the citrate.
Warning: May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0—7.5

INNOVAR® injection and SUBLIMAZE® (fentanyl) injection are available for use only upon direction of a physician.
For information relating to Contraindications, Warnings, Precautions and Adverse Reactions for SUBLIMAZE fentanyl, please turn page.

© McNeil Laboratories, Inc., 1974

SUBLIMAZE® (fentanyl) injection

Description
Each cc. contains:
Fentanyl as the citrate . . . . . 0.05 mg.
Warning—May be habit forming.
Sodium hydroxide for adjustment of pH to 4.0–7.5
FOR INTRAVENOUS OR INTRAMUSCULAR USE ONLY.

Actions SUBLIMAZE fentanyl is a narcotic analgesic with actions qualitatively similar to those of morphine and meperidine. SUBLIMAZE fentanyl in a dose of 0.1 mg. (2.0 cc.) is approximately equivalent in analgesic activity to 10 mg. of morphine or 75 mg. of meperidine. The principal actions of therapeutic value are analgesia and sedation. Alterations in respiratory rate and alveolar ventilation, associated with narcotic analgesics, may last longer than the analgesic effect. As the dose of narcotic is increased, the decrease in pulmonary exchange becomes greater. Large doses may produce apnea. SUBLIMAZE fentanyl appears to have less emetic activity than other narcotic analgesics. Histamine assays and skin wheal testing in man, as well as *in vivo* testing in dogs, indicate that histamine release rarely occurs with SUBLIMAZE fentanyl.

SUBLIMAZE fentanyl may cause muscle rigidity, particularly involving the muscles of respiration. It may also produce other signs and symptoms characteristic of narcotic analgesics including euphoria, miosis, bradycardia, and bronchoconstriction.

The onset of action of SUBLIMAZE fentanyl is almost immediate when the drug is given intravenously; however, maximal analgesic and respiratory depressant effect may not be noted for several minutes. The average duration of action of the analgesic effect is 30 to 60 minutes. Following intramuscular administration, the onset of action is from seven to eight minutes, and the duration of action is from one to two hours.

Although the duration of the respiratory depressant effect is unknown, as with other narcotic analgesics it may be considerably longer than the analgesic effect.

Indications SUBLIMAZE fentanyl is indicated:
—for analgesic action of short duration during the anesthetic periods, premedication, induction, and maintenance, and in the immediate postoperative period (recovery room) as the need arises.
—for use as a narcotic analgesic supplement in general or regional anesthesia.
—for administration with a neuroleptic such as INAPSINE® (droperidol) injection as an anesthetic premedication, for the induction of anesthesia and as an adjunct in the maintenance of general and regional anesthesia.

Contraindications SUBLIMAZE fentanyl is contraindicated in patients who are hypersensitive to the drug.

Warnings PATIENTS WHO HAVE RECEIVED *SUBLIMAZE* FENTANYL SHOULD HAVE APPROPRIATE SURVEILLANCE.

RESUSCITATIVE EQUIPMENT AND A NARCOTIC ANTAGONIST SHOULD BE READILY AVAILABLE TO MANAGE APNEA.

If SUBLIMAZE fentanyl is administered with a tranquilizer such as INAPSINE droperidol, the user should familiarize himself with the special properties of each drug, particularly the widely differing durations of action. In addition, when such a combination is used *fluids and other countermeasures to manage hypotension should be available.*

As with other potent narcotics, the respiratory depressant effect of SUBLIMAZE fentanyl persists longer than the measured analgesic effect. The total dose of all narcotic analgesics administered should be considered by the practitioner before ordering narcotic analgesics during recovery from anesthesia. It is recommended that narcotics, when required, should be used in reduced doses initially, as low as 1/4 to 1/3 those usually recommended. A neuromuscular blocking agent compatible with the patient's condition may be required to control muscle rigidity which may develop with the use of SUBLIMAZE fentanyl.

Drug Dependence: SUBLIMAZE fentanyl can produce drug dependence of the morphine type and therefore has the potential for being abused.

Severe and unpredictable potentiation by MAO inhibitors has been reported with narcotic analgesics. Since the safety of fentanyl in this regard has not been established, the use of SUBLIMAZE fentanyl in patients who have received MAO inhibitors within 14 days is not recommended.

Head Injuries and Increased Intracranial Pressure: SUBLIMAZE fentanyl should be used with caution in patients who may be particularly susceptible to respiratory depression, such as comatose patients who may have a head injury or brain tumor. In addition, SUBLIMAZE fentanyl may obscure the clinical course of patients with head injury.

Usage in Children: The safety of SUBLIMAZE fentanyl in children younger than two years of age has not been established.

Usage in Pregnancy: The safe use of SUBLIMAZE fentanyl has not been established with respect to possible adverse effects upon fetal development. Therefore, it should be used in women of childbearing potential only when, in the judgment of the physician, the potential benefits outweigh the possible hazards. There are insufficient data regarding placental transfer and fetal effects; therefore, safety for the infant in obstetrics has not been established.

Precautions *The initial dose of SUBLIMAZE fentanyl should be appropriately reduced in elderly, debilitated and other poor risk patients. The effect of the initial dose should be considered in determining incremental doses.*

Certain forms of conduction anesthesia, such as spinal anesthesia and some peridural anesthetics, can alter respiration by blocking intercostal nerves. Through other mechanisms (see Actions) SUBLIMAZE fentanyl can also alter respiration. When SUBLIMAZE fentanyl is used to supplement these forms of anesthesia, the anesthetist should be familiar with the physiological alterations involved, and be prepared to manage them in the patients selected for these forms of anesthesia. When used with a tranquilizer such as INAPSINE droperidol, blood pressure may be altered and hypotension can occur.

Vital signs should be monitored routinely.

SUBLIMAZE fentanyl should be used with caution in patients with chronic obstructive pulmonary disease, patients with decreased respiratory reserve, and others with potentially compromised respiration. In such patients, narcotics may additionally decrease respiratory drive and increase airway resistance. During anesthesia, this can be managed by assisted or controlled respiration. Postoperatively, respiratory depression caused by narcotic analgesics can be reversed by narcotic antagonists (levallorphan, nalorphine, and naloxone; consult individual prescribing information before using). Should respiration be compromised by muscle rigidity, assisted or controlled respiration and possibly a neuromuscular blocking agent will be required. The occurrence of muscle rigidity is related to the speed of intravenous injection and the incidence can be reduced by slow intravenous injection.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, pulmonary arterial pressure may be decreased. This fact should be considered by those who conduct diagnostic and surgical procedures where interpretation of pulmonary arterial pressure measurements might determine final management of the patient.

Other CNS depressant drugs (e.g. barbiturates, tranquilizers, narcotics, and general anesthetics) will have additive or potentiating effects with SUBLIMAZE fentanyl. When patients have received such drugs, the dose of SUBLIMAZE fentanyl required will be less than usual. Likewise, following administration of SUBLIMAZE fentanyl the dose of other CNS depressant drugs should be reduced.

SUBLIMAZE fentanyl should be administered with caution to patients with liver and kidney dysfunction because of the importance of these organs in the metabolism and excretion of drugs.

SUBLIMAZE fentanyl may produce bradycardia, which may be treated with atropine; however, SUBLIMAZE fentanyl should be used with caution in patients with cardiac bradyarrhythmias.

When SUBLIMAZE fentanyl is used with a tranquilizer such as INAPSINE droperidol, hypotension can occur. If this occurs the possibility of hypovolemia should also be considered and managed with appropriate parenteral fluid therapy. Repositioning the patient to improve venous return to the heart should be considered when operative conditions permit. Care should be exercised in moving and positioning of patients because of the possibility of orthostatic hypotension. If volume expansion with fluids plus other countermeasures do not correct hypotension, the administration of pressor agents other than epinephrine should be considered. Because of the alpha-adrenergic blocking action of INAPSINE droperidol, epinephrine may paradoxically decrease the blood pressure in patients treated with INAPSINE droperidol.

Adverse Reactions As with other narcotic analgesics, the most common serious adverse reactions reported to occur with SUBLIMAZE fentanyl are respiratory depression, apnea, muscular rigidity, and bradycardia; if these remain untreated, respiratory arrest, circulatory depression or cardiac arrest could occur.

Other adverse reactions that have been reported are hypotension, dizziness, blurred vision, nausea, emesis, laryngospasm and diaphoresis.

When a tranquilizer such as INAPSINE droperidol is used with SUBLIMAZE fentanyl, the following adverse reactions can occur: chills and/or shivering, restlessness, and postoperative hallucinatory episodes (sometimes associated with transient periods of mental depression); extrapyramidal symptoms (dystonia, akathisia, and oculogyric crisis) have been observed up to 24 hours postoperatively. When they occur, extrapyramidal symptoms can usually be controlled with antiparkinson agents. Postoperative drowsiness is also frequently reported following the use of INAPSINE droperidol.

Overdosage ***Manifestations:*** The manifestations of SUBLIMAZE fentanyl overdosage are an extension of its pharmacologic actions.
Treatment: In the presence of hypoventilation or apnea, oxygen should be administered and respiration should be assisted or controlled as indicated. A patent airway must be maintained; an oropharyngeal airway or endotracheal tube might be indicated. If depressed respiration is associated with muscular rigidity, an intravenous neuromuscular blocking agent might be required to facilitate assisted or controlled respiration. The patient should be carefully observed for 24 hours; body warmth and adequate fluid intake should be maintained. If hypotension occurs and is severe or persists, the possibility of hypovolemia should be considered and managed with appropriate parenteral fluid therapy. A specific narcotic antagonist such as nalorphine, levallorphan, or naloxone should be available for use as indicated to manage respiratory depression. This does not preclude the use of more immediate countermeasures. Consult the package insert for the individual narcotic antagonists for details about use.

How Supplied SUBLIMAZE® (fentanyl) injection is supplied in 2 cc. (**NDC** 0045-0180-03) and 5 cc. (**NDC** 0045-0180-05) ampuls, in packages of 12.

IMPORTANT: Complete dosage information is available in insert which accompanies each package (or on request). The drug is available only upon direction of a physician.

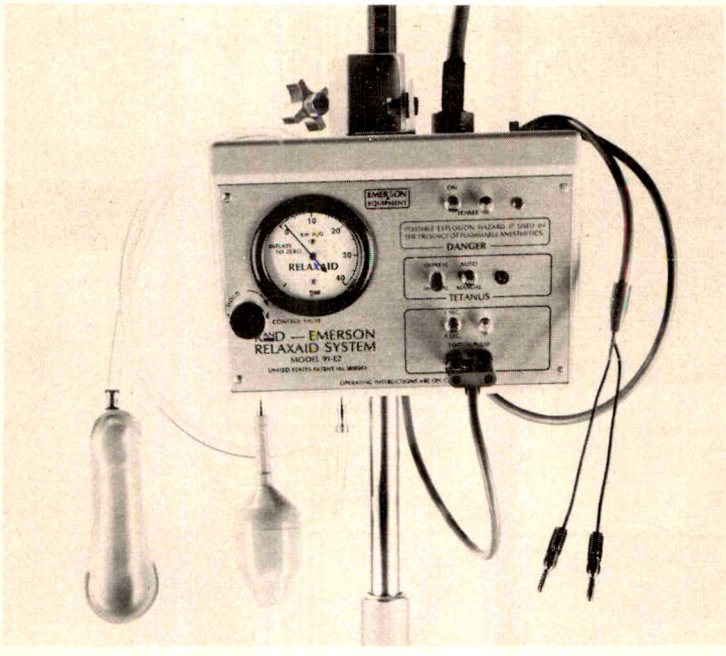
R AND D-EMERSON RELAXAID ™



for CORRECT RELAXANT DOSAGE—
AVOIDANCE OF OVERDOSE—
PROMPT RECOVERY—

The stimulator is programed to deliver pulses, through electrodes, to the ulnar nerve. A flexible pneumatic bulb is placed in the patient's hand, with his fingers held against it by tape. The bulb is then air-filled to a pressure of 20 cm. H_2O. As the fingers flex, even slightly, compression of the bulb is registered on an aneroid gauge. The pattern of these responses keeps the anesthetist informed of the relaxant's effectiveness.

The more precise monitoring provided by the RELAXAID™ enables relaxant levels to be kept adequate but without overdose. During recovery the RELAXAID™ shows the return of strength to the patient's muscles.

Outpatient Evaluation: A New Role for the Anesthesiologist

ELIZABETH A. M. FROST, MD*

Anesthesiology, although still a relatively young specialty, is expanding beyond the operating room. The author reports material savings in many areas through presurgical interviews in the outpatient department by anesthesiologists.

IN JULY 1972, in an attempt to reduce hospital stay and cost,[1-3] the Ambulatory Care Service of the Bronx Municipal Hospital Center and the Department of Anesthesiology[4,5] initiated a preadmission evaluation clinic, a project proposed as long ago as 1949.[6]

The present article describes our experiences and impressions gained in such a clinic over the past 3 years and the impact of our program on patient care and bed utilization. The clinic has now been established as a permanent part of the Outpatient Department.

METHODS AND MATERIALS

The Bronx Municipal Hospital Center is a 990-bed hospital servicing a large urban community. In 1973 and again in 1974 there were approximately 23,000 admissions, of which 65% were emergency. Of 8000 surgical operations performed, 70% were elective. The program was initially confined only to the general surgical and the gynecologic departments. Later, we expanded the facility to accommodate all services.

Patients are seen first by a surgeon in the surgical outpatient clinic and are referred to the preadmission screening clinic when scheduled for elective surgery. Referral is in no way dependent on the magnitude of the planned surgical procedure, as we have even screened patients for aortic aneurysm resection.

The referring surgeon completes a check form (figure), specifying dates of admission and operation and any special preoperative studies to be made on an outpatient basis. Urinalysis, complete blood count, SMA6 blood typing, and serum electrolytes are ordered for all surgical admissions. Chest x-ray and ECGs are ordered for patients over the age of 30 or if indicated by past medical history. These studies may also be ordered on a "STAT" basis at the discretion of the anesthesiologist at the time of interview. Papanicolaou smears are taken on all adult women patients. All test requests are stamped PRE-OP ADM to identify the source of the specimen and to promote prompt return of results. With the exception of special x-ray studies, the results of which are entered on the chart prior to admission, all other results are returned to the preadmission clinic by 1330 hr, by which time all old records on the patients have also been obtained.

A coordinating clerk in the Ambulatory Care Service schedules a clinic appointment within 10 days of the planned admission. Special radiologic procedures, such as barium studies, are scheduled for the same day. Patients are given an instruction sheet printed in both English and Spanish. They are asked to report, fasting, to the coordinating clerk's office in the hospital at 0830 hr on the day of the preadmission interview.

When patients report back to the clinic,

*Assistant Professor, Department of Anesthesiology, Albert Einstein College of Medicine, Bronx, New York 10461.

FIGURE. Check list completed for all patients attending the pre-admission screening clinic.

they are interviewed by an anesthesiologist, who reviews the current laboratory results and past history, and the check-list begun by the surgeon is completed. An internist is always present for consultation. Should any anesthetic or medical contraindication to the proposed surgical procedure be found, the patient is directed immediately to the appropriate specialty clinic and the admission is postponed. Under these circumstances, the referring surgeon, the admitting office, the operating room, and the patient are mutually informed.

For an occasional patient—as one with a recently developed upper respiratory-tract infection or even one with unexpected social obligations—we delay admission for a few days and inform those concerned. Should no contraindication to the proposed procedure be found, a final clearance check is made by the anesthesiologist on the master sheet and the patient directed back to the admitting office for final instructions. No patient leaves the clinic until final disposition has been made. We evaluate all patients, including those scheduled by the surgeon for local anesthesia; thus we are conversant with all elective procedures scheduled.

RESULTS

The system has now been operative for over 3 years, during which time we have

TABLE 1
Source of Referrals of ± 3500 Patients

Clinic	Percentage
Gynecology	45
General surgery	25
Ophthalmology	9
Urology	8
Otolaryngology	8
Orthopedic	5

seen over 3500 patients (table 1). Scheduled admission has consistently had to be withheld in about 6% of patients—most commonly because of unsuspected or uncontrolled diabetes, upper respiratory infections, severe hypertension, anemia, and pregnancy. Of these, some 17% have been cleared later the same day after repeating laboratory work, respiratory function tests, or comparing x-rays or ECGs. Nurse technicians give intensive instruction when needed to the diabetic or hypertensive patient; thus operations are often rescheduled within a week, rather than after the enormous loss of time resulting when a patient is shuffled back through normal outpatient channels.

Both preoperative and total hospital stay have been significantly reduced in comparison with data obtained from a similar group of surgical patients before establishment of the clinic.

Comparison of 89 patients over a 3-month period in 1973 with 90 nonclinic patients who had the same procedure during the same period in 1972 showed a patient-day reduction of 348 days, or an average of 3.91 days per patient (table 2).

DISCUSSION

In the relative safety of an outpatient department, where patients still maintain their identities, we have found ourselves bombarded by questions about the anesthetic technic. Much of the time of the interview is spent in allaying fears of anesthesia engendered by such ambiguous journalistic reports as the "truth serum" myth. We have found the clinic an ideal setting for explaining block and regional technics, for telling patients whether the results of their tests are normal, and whether they are in optimal physical shape for the proposed surgical procedure. When any abnormalities are revealed, the problem is always taken care of promptly.

As the clinic is directed by anesthesia staff from the recovery room and respiratory care units, continuity of anesthetic care is possible from outpatient evaluation to postanesthetic management. The availability of all laboratory reports and previous records as well as close interdepartmental cooperation have all contributed to greatly improved preoperative assessment. No more are junior house staff members required to make major preoperative decisions on evening rounds. When patients become better informed, they become lesser anesthetic risks.

Even if the surgical service has no available beds, the clinic patients are treated as semiemergency admissions and are admitted at the prearranged time to an empty bed elsewhere in the hospital. To avoid cancellation in the operating room because of overscheduling, our patients are first on the day's list. As our blood bank depends on voluntarily donated blood, the clinic provides a convenient place to explain to patients the need to find donors and the advantages to them of this system. Bed utilization has been improved by having faster turnover on surgical and gynecologic services and by increasing the census in areas not usually filled to capacity.

TABLE 2
Comparison of Patient Days, 1972 and 1973 (3-month period)

Operation	(Number of cases)	1972 (before system) Preoperative days	1972 (before system) Total days	1973 (after system) Preoperative days	1973 (after system) Total days	Days saved Preoperative days	Days saved Total days
Bilateral tubal ligation	(36)	1.97	7.63	(39) 1.33	5.26	1.64	2.37
Total abdominal hysterectomy	(33)	4.82	13.21	(23) 2.0	8.17	2.82	7.04
Breast mass excision	(21)	2.81	6.62	(27) 1.48	3.15	1.33	3.47

Comparison of patients in these 3 operative groups shows similar savings in preoperative hospital days for the extended periods. Postoperative hospital days showed a relatively comparable reduction after establishment of the clinic.

The nonhospital benefits to patients are the morning timing, which allows parents to see children off to school. The midday break also permits them to return home if necessary. Flexibility of admission combined with direct patient contact makes it possible to change an admitting date because of social pressures without losing the chance altogether for the operation. Employees are given a more exact idea of how long they can expect to be off the job.

Operating-room utilization has similarly been improved. Prior to the system, if a case were canceled after 1900 hr the previous evening, rarely could another case be prepared to fill the slot; thus the room lay fallow. Now that approximately 40% of scheduled surgical cases are being evaluated through the system, the operating-room cancellation rate has been markedly reduced.

Perhaps the biggest problem of the program is the question of reimbursement to the hospital and to the physicians involved. At present, Medicare, Medicaid, and other insurance carriers pay the Health and Hospital Corporation about $205 per inpatient hospital day at the Hospital Center. The same insurance carriers allow only $41 for outpatient presurgical evaluation at our clinic. No allowance is made for outpatient anesthesiology consultation.

Clearly, the system has become extremely costly to the hospital and physicians under present legislation. The exact cost involved is currently under review. With the passage of Public Law 92-603, preadmission evaluation for certain groups of patients will become mandatory. Insurance carriers are asking for justification of inhospital patient days. To make such programs as ours attractive to everyone, reimbursement to hospitals and physicians must become more reasonable than the present schemes allow.

We do feel, however, that the main advantages have come in improved patient care. The anesthesiologist is rightfully and legally the only physician who can fully assess a patient as an anesthetic risk. To be able to do this when time is still available to correct problems without costing the patient undue anxiety, time, or money is ideal.

No complications attributable to the clinic have occurred, and strangely enough, none of our patients have changed their minds about the procedure during the testing. Only one of our patients out of 3500 developed a ventricular arrhythmia immediately before induction and was a last-minute cancellation on the surgical schedule. In the near future, we hope that the clinic will become an integral part of an outpatient surgical unit, currently under development.

Anesthesiology, although still a relatively young specialty, is expanding rapidly out of the operating room. It is our experience that the preadmission clinic provides a natural, satisfying, and vitally important place for the modern anesthesiologist.

ACKNOWLEDGMENT

I would like to thank Dr. Richard Collens and the Ambulatory Care Service of the Bronx Municipal Hospital Center for invaluable help in the inauguration and early running of this program.

Arterial Hypoxemia Caused by Intravenous Ketamine

E. K. ZSIGMOND, MD*
A. MATSUKI, MD†
S. P. KOTHARY, MBBS‡
M. JALLAD, BS§

Ketamine given IV in a dose of 2 mg/kg caused a significant reduction in Pa_{O_2} in 7 patients spontaneously breathing with an unassisted airway. Under the same conditions, in 7 patients, ketamine (2 mg/kg IV) preceded by diazepam (0.2 mg/kg IV) also caused a reduction in Pa_{O_2} not significantly different from that caused by ketamine. In some patients, alarmingly low levels of Pa_{O_2} ($\leq$ 40 torr) were seen following ketamine administration. Based on these findings, the authors recommend that O_2 and ventilatory assistance accompany ketamine given IV for anesthesia.

SINCE its introduction into clinical anesthesia,[1,2] ketamine has geen given IV for induction and maintenance of general anesthesia without respiratory assistance and O_2 administration, in the belief that it causes neither respiratory depression nor airway obstruction from jaw relaxation.[3-5] Ketamine was even recommended as an anesthetic induction agent for patients with bronchial asthma.[6] However, no blood-gas studies or determinations of the response to CO_2 inhalation were reported to substantiate these claims.

The present study was therefore undertaken to evaluate arterial blood gases after ketamine administration.

MATERIALS AND METHODS

Patient Material.—Fourteen adult gynecology patients (ASA physical states I-II) were selected for the study. Patients gave informed consent to arterial catheterization and blood sampling. No patients were receiving any medications at the time of the study and none was pregnant. No significant differences in age, weight, or other physical characteristics were observed between the 2 groups studied. Group I (N=7) received 2 mg/kg of ketamine IV over 30 seconds; group II was given the same dose of ketamine preceded by 0.2 mg/kg of IV diazepam.

Experimental Method.—All patients received routine preoperative medication consisting of 0.15 mg/kg of diazepam and 0.007 mg/kg of atropine IM, combined with either 1.5 mg/kg of meperidine (N=4) or 0.15 mg/kg of morphine (N=8). One patient received 0.75 mg/kg of promethazine HCl with 0.75 mg/kg of meperidine and 0.008 mg/kg of atropine IM, and another patient, 0.036 mg/kg of droperidol with 0.7 μg/kg of fentanyl and 0.007 mg/kg of atropine IM.

On the patient's admission to the anesthesia study unit, a 16-gauge Teflon catheter was inserted into an antecubital vein

and 5% dextrose in 0.2% NaCl solution was started to keep the IV path open for drug injections. A 20-gauge Riley needle was inserted into the contralateral brachial artery, and a 20-minute rest period was allowed before the baseline sampling for blood gases. In the ketamine group, 2 mg/kg of ketamine was injected IV in 50 ml IV solution over 30 seconds, and blood-gas samples were taken before and at 2, 5, and 10 minutes after injection.

In the diazepam-ketamine group, first diazepam (0.2 mg/kg) was given in 30 ml of IV fluid over 30 seconds and, after 5 minutes, 2 mg/kg of ketamine was given over 30 seconds with 50 ml of IV solution. Blood-gas samples were obtained before diazepam and at 2, 5, and 10 minutes after ketamine administration. No airway support, ventilation, or O_2 were given, with the exception of 1 patient of the ketamine group who became cyanotic after the 2-minute sample was taken.

Positional changes, skin disinfection, and stimulation were avoided during the study. No additional doses of ketamine or any other IV or inhalational anesthetic agents were given, even if the patient fully awakened from sleep during the 10-minute period after ketamine administration. Additional doses of ketamine or thiamylal and muscle relaxants for endotracheal intubation were used only after the completion of blood sampling.

Laboratory Analysis.—All heparinized blood samples were immediately studied by the Radiometer Copenhagen Astrup Blood Gas Analyzer for Pao_2, $Paco_2$, and pH. Duplicate determinations were carried out on samples with a low Pao_2 by a similar analyzer, and the low Pao_2 values were found to be accurate within 5%.

Monitoring.—ECG, pulse, and blood pressure were continuously monitored throughout the study. With the exception of 1 patient in the ketamine group, chest plethysmographic recordings were also continuously taken.

RESULTS

A significant reduction in the mean Pao_2 ($p<0.01$) and elevation in the mean $Paco_2$ ($p<0.01$) occurred 2 minutes after ketamine injection (table 1). Arterial hypoxemia persisted throughout the study, and both Pao_2 and $Paco_2$ remained abnormal

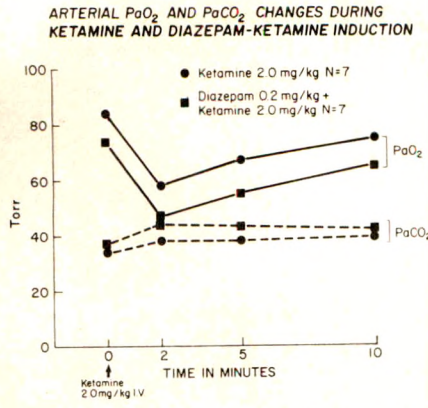

FIG. 1. Pao_2 and $Paco_2$ changes after ketamine and diazepam-ketamine administration.

even at 10 minutes after ketamine administration (fig 1). The changes from baseline values in mean Pao_2 and $Paco_2$ in the diazepam-ketamine group, with the exception of mean $Paco_2$ at 2 minutes ($p \leq 0.05$) were not significantly different from those observed in the ketamine group (table 1).

Diazepam neither antagonized nor potentiated the effect of ketamine on arterial blood gases. The changes in mean arterial pH were not statistically significant in either group. Some patients had an alarming decrease in Pao_2 (eg, from 96 to 35 torr and from 85 to 39 torr) and marked increases in $Paco_2$ (eg, from 34 to 44 torr and from 35 to 47 torr) (table 1).

A significant decrease in the respiratory rate occurred in both study groups at 3 minutes after ketamine injection (table 2). The ranges in respiratory rates in both groups indicate the varied respiratory response to ketamine. Although a few patients showed an increase in tidal volume, 50 to 60% of the patients developed apnea after ketamine injection. An example of the pattern is shown in figure 2. Pretreatment with diazepam did not alter the incidence or duration of apnea.

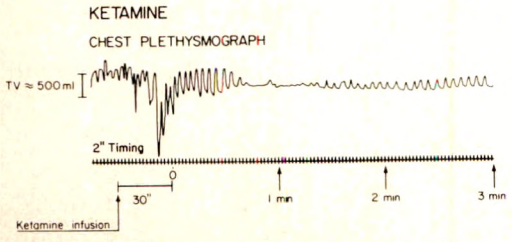

FIG 2. Typical chest-plethysmographic tracing from a patient after ketamine administration.

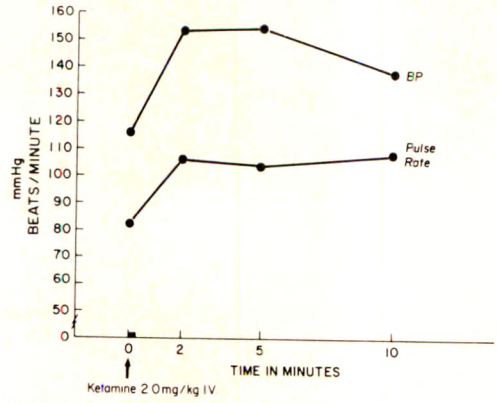

FIG 3. Blood pressure and pulse rate changes following IV ketamine administration.

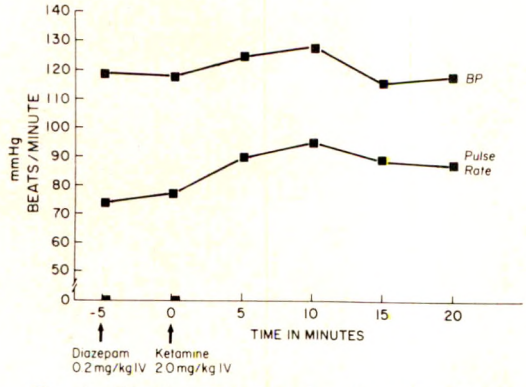

FIG 4. Blood pressure and pulse rate changes following diazepam-ketamine administration.

Arterial blood pressure and pulse rate were elevated in the ketamine group (fig 3). Diazepam reduced these effects of ketamine (fig 4). No arrhythmias or airway obstruction were observed in any patient. Analysis of circulatory effects will be presented in a later publication.

DISCUSSION

Despite reports on the lack of respiratory depressant effect of ketamine[7-9] and its recommendation as an induction agent for patients with airway and respiratory problems,[2,4,6] marked arterial hypoxemia was observed in our studies. The concomitant increase in $Paco_2$ makes it likely that ketamine directly depresses the respiratory center. Indeed, several patients became apneic for more than 30 seconds following ketamine administration.

Regardless of the exact mechanism of the arterial hypoxemia induced by ketamine, it must be promptly corrected, since it results in severe oxyhemoglobin desaturation (eg, 98 to 67% and 95 to 71%) in some patients. If this alarming result is allowed to persist, even briefly, in patients with anemia and/or with reduced cardiopulmonary reserve, it may result in morbidity or mortality.

Therefore, we recommend adequate ventilatory assistance and O_2 administration during induction of anesthesia either with ketamine or diazepam-ketamine combination. Arterial blood gases, catecholamines, O_2 uptake, and CO_2 response, especially in patients with abnormal cardiopulmonary reserve, should be studied further to elucidate the mechanism of arterial hypoxemia following ketamine administration in man.

ACKNOWLEDGMENT

We are grateful to all the patients who volunteered for the study and to Parke, Davis and Company for their financial support of our investigations. We are also indebted to the staff of the University of Michigan Medical Center Department of Gynecology and Obstetrics, who allowed us to study their patients.

Factors Affecting A-aDo_2 After Open-Heart Surgery

ATSUO SARI, MD*
YOSHIAKI OKUDA, MD†
HIROSHI TAKESHITA, MD‡
TATSUROH ODA, MD§
Ube, Yamaguchi, Japan‖

Intrapulmonary shunt, cardiac output, and O_2 consumption as factors contributing to alveolar-arterial O_2 tension difference (A-aDo_2) were tested in 11 patients after open-heart surgery. A-aDo_2 was well correlated with intrapulmonary shunt, as expected, but no correlation was found between cardiac index (CI) and intrapulmonary shunt. When total shunt (venous admixture) was above 11%, there was an inverse correlation between A-aDo_2 and CI, and it was observed that CI falling below 2.5 L/min/sq m contributed significantly to the enlargement of A-aDo_2. Low Pao_2 (<65 torr, breathing room air) was characterized by larger arterial-mixed venous O_2 content difference than high Pao_2 (>65 torr, on room air), indicating that A-aDo_2 was influenced by cardiac output relative to metabolic demand. Intrapulmonary shunt played a main role in increasing A-aDo_2 after open-heart surgery, and systemic factors, including changes in cardiac output and O_2 consumption, also contributed to development of hypoxia.

OUR previous investigation[1] demonstrated a gradual fall in arterial O_2 tension (Pao_2) following open-heart surgery and proposed criteria for postoperative respiratory management. Since Kelman and coworkers[2] proposed that decrease in cardiac output ($\dot{Q}t$) leads to hypoxia, several investigators[3-5] have directed their attention to $\dot{Q}t$ as a possible factor affecting postoperative arterial oxygenation, but have found no consistent relationship postoperatively between $\dot{Q}t$ and alveolar-arterial O_2 tension difference (A-aDo_2).

The present study examines possible relationships between increased A-aDo_2 and intrapulmonary shunt, $\dot{Q}t$, and O_2 consumption ($\dot{V}o_2$) in postoperative open-heart patients.

METHOD

The 11 patients studied represented 2 cases of atrial septal defect, 4 cases of ventricular septal defect, 4 cases of tetralogy of Fallot, and 1 case of mitral stenosis. Ages ranged from 5 to 21 (average 12) years (table 1). All survived except 1 tetralogy patient, who died of heart failure on the 41st postoperative day.

Anesthesia.—Premedication consisted of atropine sulfate (0.02 mg/kg, maximal dose 0.5 mg) and nitrazepam* (5 to 10 mg) in adults or pethidine (meperidine) (1 mg/kg) in children. Anesthesia was induced with thiopental sodium (5 mg/kg in adults

TOF = tetralogy of Fallot.

or with halothane-N_2O in children. Intubation was facilitated by succinylcholine. Anesthesia was maintained with 0.5 to 1% halothane and N_2O-O_2 (2:2) in a semi-closed system. In all cases, a disposable-sheet bubble oxygenator with roller pump was used.

Measurements. — Teflon catheters were placed percutaneously in either a radial or brachial artery and in the superior vena cava. The venous catheter was moved into the pulmonary artery before chest closure. The catheters were used for arterial and mixed venous blood sampling, pressure monitoring, and $\dot{Q}t$ determination. The $\dot{Q}t$ was determined by the dye-dilution technic, with a single injection of indocyanine green. A densitometer† and a Harvard‡ infusion withdrawal pump were used.

Measurements were made at the end of operation and 4, 8, and 24 hours later, with patients breathing air or 100% O_2. Arterial and mixed venous P_{O_2}, P_{CO_2}, and pH were measured by IL meter§ at 37 C within 10 minutes of collection.

Calculations.—Total shunt (venous admixture $\dot{Q}_{VA}/\dot{Q}t$)[1] and true shunt ($\dot{Q}s/\dot{Q}t$), with patients breathing air and 100% O_2, respectively, has been widely used to detect the contribution of ventilation/perfusion inequalities to the $\dot{Q}_{VA}/\dot{Q}t$.[4-9] The $\dot{Q}_{VA}/\dot{Q}t$ consists of the anatomic shunt, atelectasis, ventilation/perfusion inequalities, and diffusion gradient. The $\dot{Q}s/\dot{Q}t$ represents the blood flow through anatomic shunt and atelectasis. The diffusion gradient across normal alveolar membranes is negligible at alveolar O_2 tension (P_{AO_2}) >100 torr.

O_2 content in arterial blood (Ca_{O_2}) and in mixed venous blood ($C\bar{v}_{O_2}$) was calculated from the following equation:

O_2 content = 1.39 × Hb × S_{O_2} + 0.0031 × P_{O_2}, where 0.0031 is the solubility coefficient for O_2 in blood at 37 C and S_{O_2} is O_2 saturation; read from a blood-gas calculator,[10] this was estimated to be 1 while 100% O_2 was breathed.

$\dot{Q}_{VA}/\dot{Q}t$ was calculated from the following equation:

$$\frac{\dot{Q}_{VA}}{\dot{Q}t} = \frac{C\acute{c}_{O_2} - Ca_{O_2}}{C\acute{c}_{O_2} - C\bar{v}_{O_2}}$$

where $C\acute{c}_{O_2}$ is end-pulmonary capillary O_2 content, and is calculated on the basis of the end-pulmonary capillary O_2 tension ($P\acute{c}_{O_2}$) being equal to the P_{AO_2}.

The $\dot{Q}s/\dot{Q}t$ was calculated from the following modified equation:[11]

$$\frac{\dot{Q}s}{\dot{Q}t} = \frac{0.0031\ (P_{AO_2} - Pa_{O_2})}{0.0031\ (P_{AO_2} - Pa_{O_2}) + Ca_{O_2} - C\bar{v}_{O_2}},$$

where P_{AO_2} is calculated from the alveolar/air equation by assuming a respiratory exchange quotient of 0.76.[12] The $\dot{V}_{O_2}$ was calculated as the product of $\dot{Q}t$ and arterial-mixed venous O_2 content difference ($Ca_{O_2} - C\bar{v}_{O_2}$).

a: arterial blood
$\acute{c}$: capillary blood
$\bar{v}$: mixed venous blood
A: alveolar gas
BT: body temperature
CI: cardiac index
A-aDO_2: alveolar-arterial tension difference
Ca_{O_2}: arterial O_2 content
$C\acute{c}_{O_2}$: capillary O_2 content
$C\bar{v}_{O_2}$: mixed venous O_2 content
$\dot{Q}s/\dot{Q}t$: true shunt
$\dot{Q}t$: cardiac output
$\dot{Q}_{VA}/\dot{Q}t$: total shunt
S_{O_2}: % saturation of Hb with O_2
$\dot{V}_{O_2}$: O_2 consumption

*Significant as compared to end operation.

Statistical significance was determined by Student's *t*-test for unpaired data.

RESULTS

Mean values and standard error for all variables are shown in tables 2 and 3. No statistical significance at different times was found except increased pH at 24 hours. Metabolic alkalosis after open-heart surgery has been discussed elsewhere.[1]

Using the pooled values, factors affecting A-aD_{O_2} were examined. A positive linear correlation was observed between A-aD_{O_2} and $\dot{Q}_{VA}/\dot{Q}t$ ($r=0.863$, $p<0.01$) or $\dot{Q}s/\dot{Q}t$ ($r=0.516$, $p<0.01$). Two regression lines were derived from the data: $Y=40X-341.2$ and $Y=1.77X+10.39$ on air and 100% O_2, respectively, where Y = A-aD_{O_2}, $X=\dot{Q}_{AV}/\dot{Q}t$ or $\dot{Q}s/\dot{Q}t$ (fig 1). There was no significant difference between $\dot{Q}_{VA}/\dot{Q}t$ and $\dot{Q}s/\dot{Q}t$ at any postoperative period.

No significant correlation was found between CI and $\dot{Q}_{AV}/\dot{Q}t$ ($r=0.05$, $p>0.1$) or $\dot{Q}s/\dot{Q}t$ ($r=0.175$, $p>0.05$) nor between CI and A-aD_{O_2} either on air or 100% O_2.

However, when values were arbitrarily divided into 2 $\dot{Q}_{VA}/\dot{Q}t$ groups—(I) >11% and (II) <10% (fig 2)—there was an inverse correlation in group I between A-aD_{O_2} and CI ($r=-0.502$, $p<0.01$), the regression line being $Y=-29.4X+131.4$ on logarithmic graph, where $Y=\log_{10}$ (A-aD_{O_2}) and $X=\log_{10}$ (CI). This equation was transformed into $Y=288X^{-1.864}$ on arithmetic graph, where Y = A-aD_{O_2} and X = CI ($2\leqq X\leqq 6$), and appeared as a curved line fitting the values in figure 2. There was no significant correlation in group II between A-aD_{O_2} and CI ($r=-0.118$, $p>0.1$), nor was a consistent relation between A-aD_{O_2} and CI detectable, although the same division of values according to the amount of $\dot{Q}s/\dot{Q}t$ was made.

Values at the end of the surgical procedure and at 8 and 24 hours postoperatively were also divided into 2 groups: (I) with Pa_{O_2} values <65 torr and (II) Pa_{O_2} >65

*Significant as compared to end operation.

torr while breathing air (table 4). There was a significant difference in $Cao_2 - C\bar{v}o_2$ between the 2 groups both on air and 100% O_2. Group I was characterized by higher $\dot{Q}_{VA}/\dot{Q}t$ than group II, even though the $\dot{Q}s/\dot{Q}t$ was essentially the same.

DISCUSSION

In our previous study,[1] a gradual fall in Pao_2, whether breathing 40% O_2 or air, was consistently observed and indicated the need for further study on factors affecting A-aDo_2.

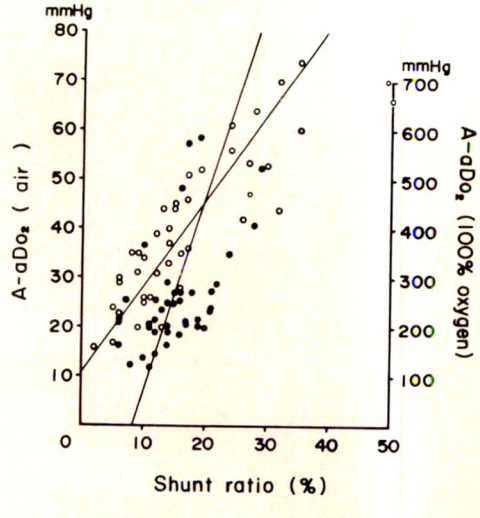

FIG 1. Relationship between A-aDo_2 and intrapulmonary shunt when breathing air ($\dot{Q}_{VA}/\dot{Q}t$, open circles) or 100% O_2 ($\dot{Q}s/\dot{Q}t$, solid circles).

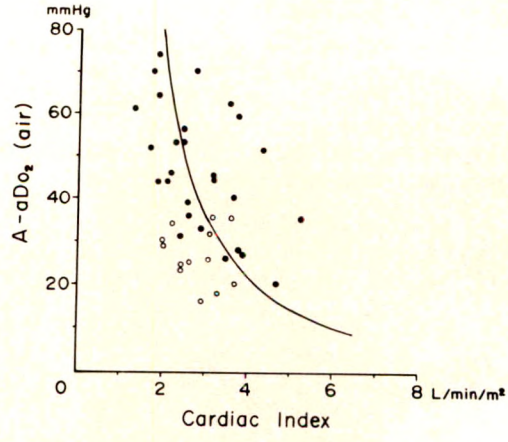

FIG 2. Relationship between A-aDo_2 and cardiac index. Solid circles = values with $\dot{Q}_{VA}/\dot{Q}t$ >11% and open circles = <10%. Curve was derived, when $\dot{Q}_{VA}/\dot{Q}t$ was >11%, from equation:

$Y = 288X^{-1.864}$ $(2 \leqq X \leqq 6)$, Y = A-aDo_2
X = cardiac index

Intrapulmonary Shunt. — Marshall and Wyche[7] indicated that postoperative hypoxemia may be divided into early and late types. Early hypoxemia progressively improved to normal within 3 to 4 hours postoperatively, suggesting that anesthesia contributed to increase in intrapulmonary shunt during the early postoperative period. Such an improvement was not observed in our present study.

Our results are in partial agreement with those of Colgan and Mahoney,[4] who also observed no appreciable effect of anesthesia on $\dot{Q}_{VA}/\dot{Q}t$ or $\dot{Q}s/\dot{Q}t$ at 1 to 4 hours following major abdominal surgery. We believe that in this study, anesthesia did not contribute significantly to intrapulmonary shunt. As expected, a positive linear correlation was obtained between A-aD_{O_2} and $\dot{Q}_{VA}/\dot{Q}t$ or $\dot{Q}s/\dot{Q}t$. Several investigators[6,8,13,14] have emphasized atelectasis or ventilation/perfusion inequalities as the primary cause of increased A-aD_{O_2}. The present study is compatible with the report of Hedley-Whyte,[6] who concluded that the most important single cause of postoperative intrapulmonary shunt in cardiac patients was atelectasis as evidenced by the presence of large $\dot{Q}s/\dot{Q}t$ and suggested that hypoxemia was generally present after all major operations.

Our finding of no significant difference between $\dot{Q}_{VA}/\dot{Q}t$ and $\dot{Q}s/\dot{Q}t$ at any postoperative period corroborates those of Muneyuki[9] and of Markello and associates.[15] The latter proposed that this fact may be due to an area of low ventilation/perfusion ratio becoming atelectatic while breathing 100% O_2. This proposal awaits further study.

Cardiac Output.—Kelman[2] theorized that reduction in $\dot{Q}t$ alone may account for increase in A-aD_{O_2} without changes in the underlying shunt. Subsequently, Prys-Roberts' group[16] confirmed Kelman's study in anesthetized man, and Modell and Milhorn[17] observed that a reduction in $\dot{Q}t$ produced an increase in A-aD_{O_2} in thoracotomized dogs. These studies indicated that the alteration of $\dot{Q}t$ must be considered as a significant factor affecting arterial oxygenation. The effect of altered $\dot{Q}t$ on arterial oxygenation can be predicted when $\dot{V}_{O_2}$ and intrapulmonary shunt remain constant.

The following is derived from shunt and Fick equations:

$$C\acute{c}_{O_2} - Ca_{O_2} = \frac{\dot{V}_{O_2}}{\dot{Q}t} \times \frac{R}{1\text{-}R}$$

where R is $\dot{Q}_{VA}/\dot{Q}t$ or $\dot{Q}s/\dot{Q}t$. Using this formula, Philbin[5] predicted the magnitude of decrease in Ca_{O_2} associated with the reduction of $\dot{Q}t$. However, when the content difference $C\acute{c}_{O_2}$ —Ca_{O_2} is converted to tension difference A-aD_{O_2}, the inverse relationship to $\dot{Q}t$ is hyperbolic while breathing 100% O_2 but assumes a complex nonlinear form, in consequence of the shape of the O_2-dissociation curve, while breathing air. Although some observers[3-5] reported no consistent relationship between $\dot{Q}t$ and A-aD_{O_2}

during the postoperative period, we found an inverse correlation when $\dot{Q}_{VA}/\dot{Q}t$ was >11%, but none when <10%.

The failure to demonstrate correlation between A-aDo_2 and $\dot{Q}t$ with 100% O_2 warrants further explanation. One possible explanation is that a change in $\dot{Q}t$ may be accompanied by the same directional change in $\dot{Q}s/\dot{Q}t$ as that which counteracts to low Pao_2 produced by the reduction of $\dot{Q}t$.[18-20] We are unaware of any report regarding the correlation between $\dot{Q}t$ and $\dot{Q}_{VA}/\dot{Q}t$ in postoperative patients.

Marshall and Wyche[7] state that $\dot{Q}t$ is not an important determinant of intrapulmonary shunt. Discrepancy among these investigations may be due to complex interrelationships between $\dot{Q}t$, intrapulmonary shunt, and $\dot{V}o_2$. The present study, however, clearly showed that low CI (below 2.5 L/min/sq m) significantly contributed to enlargement of A-aDo_2 when $\dot{Q}_{VA}/\dot{Q}t$ was large.

Oxygen Consumption.—In spite of the great interest in the effect of $\dot{V}o_2$ on arterial oxygenation after operations, little data exist on the relationship between $\dot{V}o_2$ and A-aDo_2. Our low Pao_2 group showed a significantly larger $Cao_2 - C\bar{v}o_2$ and higher $\dot{Q}_{VA}/\dot{Q}t$ than the high Pao_2 group. However, there was no significant difference in $\dot{Q}s/\dot{Q}t$ between the 2 groups. Therefore, low Pao_2 may be one of the factors related to the widening $Cao_2 - C\bar{v}o_2$.

Although no statistically significant difference in $\dot{V}o_2$ was found between the 2 groups, the mean value in the low Pao_2 group was greater than in high Pao_2 group, as compared with the changes in CI. Therefore, it is suggested that a $\dot{Q}t$ which is not sufficient for metabolic demand may contribute to low Pao_2. An increase in the $\dot{V}o_2$ in the postoperative period of open-heart surgery may be caused by rise in body temperature, shivering, restlessness, an increase in the work of breathing, or a change in pH. However, we found no significant difference in such factors increasing in $\dot{V}o_2$ between the 2 groups.

In noncardiac patients,[3] there was no correlation between $\dot{V}o_2$ and Pao_2, with or without shivering, in the early postoperative period, since increased $\dot{V}o_2$ may be counteracted by increased $\dot{Q}t$. On the other hand, Kirklin and Rastelli[20] pointed out that $\dot{Q}t$ relative to metabolic demand is reduced soon after cardiac surgery, a finding comparable to our results, in that $\dot{V}o_2$ is larger in the low Pao_2 group, and may be a possible factor in increasing A-aDo_2 after open-heart surgery.

In our study the low Pao_2 group showed a higher $\dot{Q}_{VA}/\dot{Q}t$ than the high Pao_2 group, even though the $\dot{Q}s/\dot{Q}t$ was essentially the same in the 2 groups. These differences may be the result of impaired diffusion due to relatively low inspired O_2 concentration.

It has been generally accepted that diffusion gradient has a significant role in producing A-aDo_2 only when the PAo_2 is well below normal. Fordham[14] examined the diffusion effect in patients after open-heart surgery and concluded that the pulmonary diffusion effect, if present, played only a small part in hypoxemia after such operations. However, Hedley-Whyte[6] suggested that if the distribution of ventilation is sufficiently uneven, one must assume that a diffusion effect adds to the shunt because in the least ventilated alveoli, the PAo_2 may be sufficiently low, or the alveolar membranes sufficiently thickened, to establish a diffusion gradient. We prefer to think of this manifestation as a result of uneven distribution of ventilation.

We conclude that intrapulmonary shunt plays an important role in increasing postoperative A-aDo_2 and causes further development of hypoxia, especially when it is accompanied by a reduction in CI below 2.5 L/min/sq m or by a relative increase in $\dot{V}o_2$ not compensated by an increase in $\dot{Q}t$.

Hepatic Clearance of Lidocaine During N_2O Anesthesia in Dogs

ROBERT G. BURNEY, MD*
COSMO A. DiFAZIO, PhD, MD†
Charlottesville, Virginia‡

Lidocaine catabolism under N_2O anesthesia was evaluated in 5 dogs given a lidocaine infusion of 2 mg/kg/min for 20 minutes. Comparison of results with those of a prior similar study with halothane anesthesia showed catabolism of lidocaine to be significantly faster in the animals given N_2O. The extraction ratio for lidocaine, which did not vary with its arterial concentration, was significantly lower with halothane than with N_2O. Decreased hepatic catabolism of drugs such as lidocaine should be anticipated in patients anesthetized with potent inhalation agents such as halothane.

LIDOCAINE is frequently administered together with general anesthetics, either for the enhancement of the anesthetic state or to control cardiac arrhythmias. The resultant blood level of lidocaine is a function principally of the dose administered, the distribution of the drug, and the rate of hepatic elimination. Hepatic elimination of lidocaine can be changed by alterations in hepatic blood flow[1,2] and drug effects on hepatic enzymes.[3,4] Although inhalational anesthetic agents are known to affect hepatic blood flow[5,6] and the catabolism of drugs,[7,8] the effect of concomitantly administered inhalational agents on the catabolism of lidocaine has not been defined.

This study was designed to determine if the disappearance of lidocaine during N_2O anesthesia differs from that observed under halothane,[3] and if lidocaine extraction varies with the blood concentration of the drug itself.

METHOD

Five mongrel dogs weighing 15 to 20 kg were anesthetized with an 80% N_2O-O_2 (0.43 MAC)-curare technic. Ventilation was controlled with an Emerson ventilator. The femoral artery was cannulated and the abdomen opened. A catheter was passed from the external jugular into a hepatic vein under direct vision. Arterial blood pressure was recorded on a Model 7 Grass polygraph. A fluid load of 500 ml of 5% dextrose/lactated Ringer's solution was given before the experiment. Heparinized blood samples (6 ml) were drawn from the femoral artery (considered equivalent to blood in the hepatic artery) and the hepatic vein in a control state, and 30, 60, 90, and 120 minutes after a 2 mg/kg/min dose of lidocaine was infused over a 20-minute period.

Arterial blood gases were determined using a Radiometer Blood Gas Analyzer, with the $Paco_2$ maintained at 25 to 30 torr. Lidocaine was quantitated with a Hewlett-Packard 5750 gas chromatograph equipped with a flame-ionization detector, using a previously described method.[9]

Extraction of lidocaine by the liver was calculated from the concentration gradient of the drug across the liver and is expressed

as a fraction of drug removed. Drug disappearance data was plotted on semilog coordinates by the least-squares technic on a programmable calculator. Significant differences of blood-lidocaine concentration at 30, 60, and 120 minutes in the N_2O and halothane experiments and of the k (disappearance rate constant) values calculated from the disappearance curves were determined by Student's t-test. The measured concentrations of lidocaine existing after the early distributional phase in each study were fitted to the equation $[L] = ae^{-kt}$.

RESULTS (table 1 and figure)

The disappearance of lidocaine in the presence of N_2O was significantly faster than that previously reported in dogs anesthetized with halothane. The mean ($\pm$ SD) of the k values with N_2O in this experiment was 0.0122 ± 0.0013 (n=5). In contrast, the mean k value for all dogs previously studied using halothane was 0.0081 ± 0.003 (n=5), k values significantly different at $p<0.05$. The mean extraction ratio of lidocaine during administration of N_2O-curare was 0.57 $\pm$ 0.11. This is more than a twofold increase over the values previously obtained during halothane anesthesia. The hepatic extraction ratio for lidocaine during N_2O anesthesia was unaffected by lidocaine concentration over a wide range.

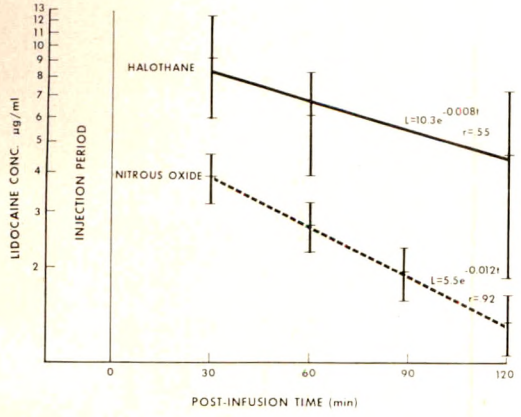

FIGURE. Lidocaine disappearance curves (arterial blood). The early distribution phase is omitted. Blood concentrations were significantly lower when N_2O was the anesthetic ($p<0.01$ at 30 min, $p<0.05$ at 60 and at 120 min).

DISCUSSION

The only significant differences between the 2 groups studied, other than the choice of anesthetic agent were: (1) the halothane group breathed spontaneously, with $Paco_2$ between 40 and 50 torr, whereas the N_2O animals were ventilated, with $Paco_2$ between 25 and 30 torr, and (2) the N_2O group also received curare while the halothane group received only succinylcholine for intubation.

Mechanical ventilation decreases splanchnic blood flow, probably on a mechanical basis.[6] However, this should decrease the differences between our study groups. Carbon dioxide is known to affect splanchnic flow.[5,6] However, the higher $Paco_2$ during halothane anesthesia should increase hepatic flow.[6] Muscle relaxants per se are not known to affect hepatic flow. Ganglionic blocking agents do not affect splanchnic resistance,[5] and this property of curare should not have affected our results. Thus, the major differences between the present experiment and the previous study should tend to decrease the observed differences between the 2 groups.

The disappearance of lidocaine from blood after the initial distribution phase is primarily dependent on hepatic removal. Thus the differences observed between the removal rate during halothane and N_2O anesthesia could result from alterations in hepatic removal through effects on hepatic blood flow or on the hepatic enzymes. Hepatic enzymes in turn may be affected by membrane permeability, availability of cofactors, enzyme saturation, and inhibition by other drugs.

Lidocaine removal has been shown to be directly affected by hepatic blood flow. Stenson's group[1] observed that in cardiac patients receiving a constant IV infusion of lidocaine, higher lidocaine blood levels occurred when cardiac output (and presumably hepatic blood flow) was decreased. Benowitz and associates[2,10] observed that with the decreased hepatic blood flow produced by norepinephrine infusion, a decreased rate of hepatic removal of lidocaine occurred. Conversely, an increased rate of hepatic removal of lidocaine was produced in the presence of an increased hepatic blood flow resulting from the infusion of isoproterenol.

Halothane[6,11,12] and cyclopropane[13] have been shown to reduce hepatic blood flow in man and animals, one group[12] suggesting that blood flow decreases with increasing depth of anesthesia. Certainly part of the difference in the rate of hepatic removal of lidocaine with N_2O or halothane present can be attributed to the differences in hepatic blood flow produced by the inhalational anesthetics. While absolute values of changes in hepatic blood flow in animals with any fixed anesthetic concentration remains to be defined, an approximation might be obtained by assuming that the hepatic blood flow in animals receiving halothane is 25% less than in those receiving N_2O, a value comparable to the 20 to 30% differences observed in anesthetized human volunteers.[6,13] Disappearance rate and half-life (T_{50}) calculations for lidocaine under such conditions (table 2) result in a T_{50} of 77 minutes for lidocaine and differs from the 99-minute T_{50} calculated from the prior halothane experiment. It seems plausible that the decreased disappearance rate for lidocaine under halothane anesthesia is contributed to by factors other than the reduction in hepatic blood flow.

Inhalational anesthetics have in addition been suspected of altering the catabolism of many drugs. A high concentration of the anesthetics in the lipid-rich microsomes principally involved in drug biotransformation is to be expected on the basis of lipid solubility of the anesthetics. Baekland and Greene[14] demonstrated that pentobarbital metabolism by liver homogenates was decreased by the addition of diethyl ether. Brown[7,15] documented *in vitro* dose-dependent inhibition of oxidative metabolism of barbiturates and aminopyrine by both halothane and methoxyflurane, while Sawyer and associates[8] suggested that an increase in halothane concentration decreases hepatic halothane removal by either enzyme saturation or substrate inhibition.

The differences in lidocaine disappearance found in the present studies suggest that halothane may decrease the removal of lidocaine by an effect on hepatic microsomes in addition to the expected effect on hepatic blood flow, although the exact mechanism remains to be defined, and may be the noncompetitive dose-dependent effect seen by Brown[7] with halothane on barbiturate destruction. However, regardless of which mechanism dominates, decreased hepatic removal of drugs such as lidocaine should be anticipated when administered to patients anesthetized with potent inhalational anesthetic agents.

TABLE 2

Values of k^* for N_2O-Anesthetized and Halothane-Anesthetized Animals

Anesthetic	Rate constant (k)	Half-life (T_{50}), min
N_2O (observed values)	0.012	59
N_2O (corrected for an assumed 25% reduction in $\dot{Q}$)	0.009	77
Halothane (observed values)	0.007	99

*k = disappearance rate constant; measured from least-square plot (figure).

For a theoretical circumstance in which the liver blood flow of the N_2O anesthetized animals is reduced by an arbitrary 25%, k is calculated from the equation $k = \frac{\dot{V}_d}{\dot{Q}.E}$, assuming no change in $\dot{V}_d$ and E occurs with the reduction in flow. ($\dot{V}_d$ = volume of distribution, $\dot{Q}$ = hepatic blood flow, E = extraction fraction.) The half-life (T_{50} is calculated from the equation $T_{50} = \frac{\ln 2}{k} = \frac{0.693}{k}$.

The Lateral Sitting Position for Neurosurgery

FRANCISCO GARCIA-BENGOCHEA, MD*
EDWIN S. MUNSON, MD†
JAMES V. FREEMAN, MD‡
Gainesville, Florida‖

Over the past 20 years, more than 300 patients have been anesthetized in the lateral sitting position during neurosurgical procedures in the posterior fossa and the cervical and upper thoracic spine. Since the patient can be placed quickly and easily in the horizontal position, the lateral sitting position has a number of advantages over the conventional sitting position, particularly in the treatment of arterial hypotension and venous air embolism. Furthermore, with the patient in the lateral horizontal position, the surgical procedure can be completed satisfactorily.

DURING the past 20 years, the lateral sitting position has been used satisfactorily for operations in the posterior fossa and the cervical and upper thoracic spine. Since the initial report 19 years ago,[1] a number of technical modifications have been introduced, some of which were reported[2] in 1963 and others of which have been incorporated recently. This paper describes the technic for the anesthesiologist as it is presently carried out and discusses the method as one of the therapeutic measures for managing arterial hypotension and venous air embolism during operations on patients in the sitting position.

DESCRIPTION OF TECHNIC

The main steps of our method are as follows:

1. The patient is placed supine on the operating table (fig 1A) for insertion of intravascular catheters, application of monitoring equipment, induction of anesthesia, and tracheal intubation. Elastic stockings may be applied to the patient's legs.

2. The skull clamp is fixed to the patient's head.

3. The operating table is maximally "flexed" by manipulating the S-handle on the right side of the H-frame, while the seat is kept almost horizontal by simultaneous and proportional motions in the reverse Trendelenburg direction through activation of the T-handle on the left side of the H-frame (fig 1B).

4. The back section is elevated further to about 80° from the horizontal by activating the S-handle on the right side of the H-frame (fig 1C). The flat headrest of the table is removed and replaced by the attachment for the skull clamp (fig 1D).

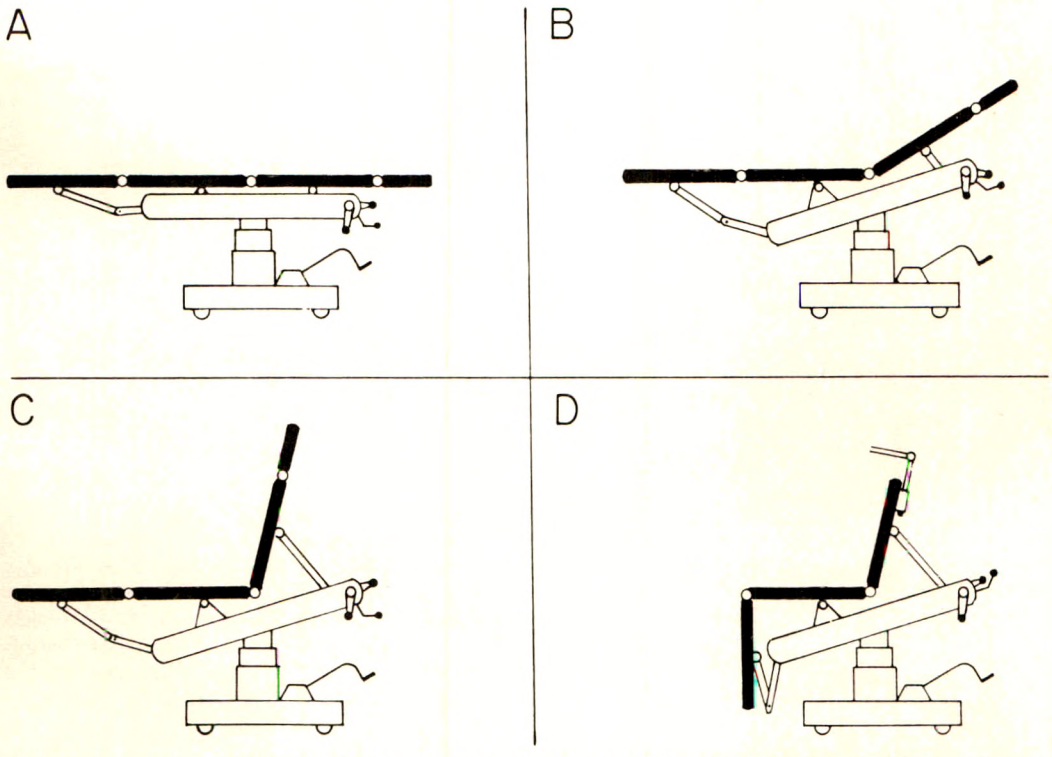

FIG 1. Schematic drawing showing the manipulations required to convert the table H-frame and table top for use with the lateral sitting position (see text for details). The patient is not represented but can easily be imagined.

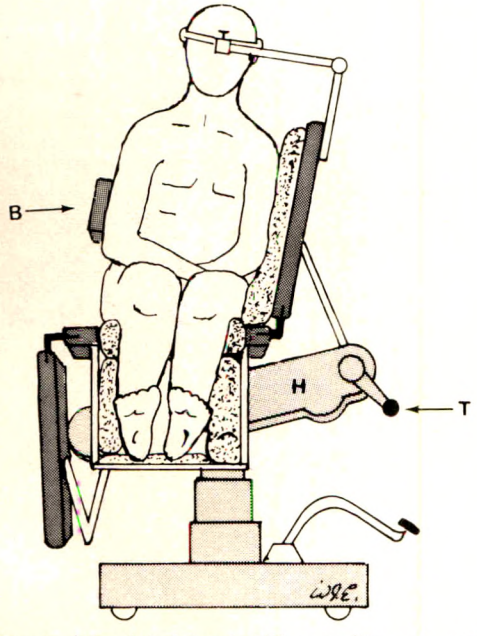

FIG 2. The left lateral sitting position, as seen from left side of operating table. H = main movable frame of table. T = handle for moving in Trendelenburg direction and reverse. B = backrest.

5. While the surgeon or one assistant manually holds the head, the patient is rotated to become perpendicularly oriented to the long axis of the operating table. The shoulder and arm leaning against the back section of the operating table are thoroughly padded with foam rubber or similar materials. In children and short patients, additional padding is placed under the buttocks to elevate the head to the level of the skull clamp attachment.

6. The special backrest B* (fig 2 and 3) is attached to the side rail of the back section and the operating table is tilted about 5 to 10° toward the dorsum of the patient.

7. The skull clamp is connected to the table attachment and the head fixed in the desired position (fig 2 and 3).

8. The lower extremities are well padded to protect them from pressure phenomena against the supporting surfaces, as well as from pressure against the opposite lower extremity. The legs and feet are supported

*Specifications for the backrest and foot attachment available from author on request.

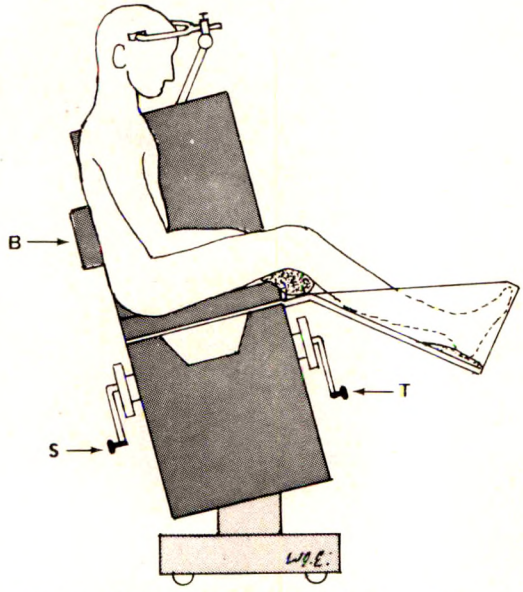

FIG 3. Patient in left lateral sitting position, as seen from foot end of operating table. S = handle for moving back, seat, and foot section of table top. B and T as in figure 2.

by a specially designed foot attachment* (fig 2 and 3). This can be adjusted at different angles of elevation between the plane of the seat section and 90° below it.

*Specifications for the backrest and foot attachment available from author on request.

9. The regular foot section of the operating table is completely flexed, thus transforming the table into the configuration of a chair (fig 1D).

10. A bar for holding the drapes is attached to the side rail of the back section of the operating table at the level of, and in front of, the head. A second bar is attached below the first at the level of the heart for support of pressure transducers (fig 4). When the surgical preparation and draping of the operative field are completed, the drapes are brought over and around the second bar, creating a "tent" that permits excellent access to the patient's face, neck, trunk, and extremities.

Neither instrument tables nor stands, IV poles, or other equipment should have any attachment to the drapes or operating table, but should be placed conveniently so they will not limit or hinder any motions for lowering the head. In the event the head must be lowered, the anesthesiologist manipulates the T-handle for the control of the Trendelenburg motion, bringing the head down toward the horizontal as desired (fig 5). If the table then is too low to allow adequate range of Trendelenburg motion of the H-frame, the pedal for raising the height of the whole table must be activated by the surgeon or one of his assistants to obtain the desired height. The surgical procedure

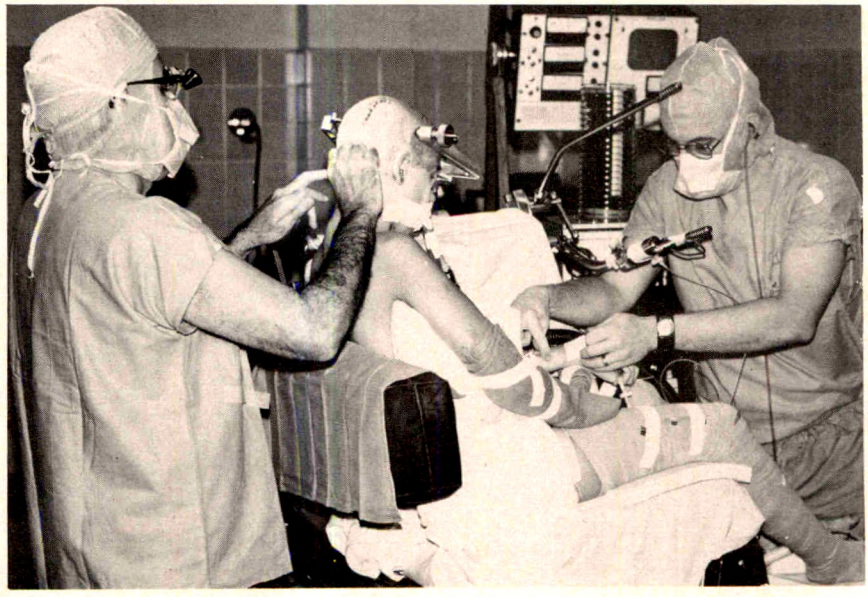

FIG 4. Surgeon (left) and anesthesiologist (right) just before preparing and draping patient for a right suboccipital craniectomy. Backrest and supporting bars for drapes and arterial transducers are shown. Lateral sitting position gives anesthesiologist excellent access both to patient's airway and to monitoring equipment.

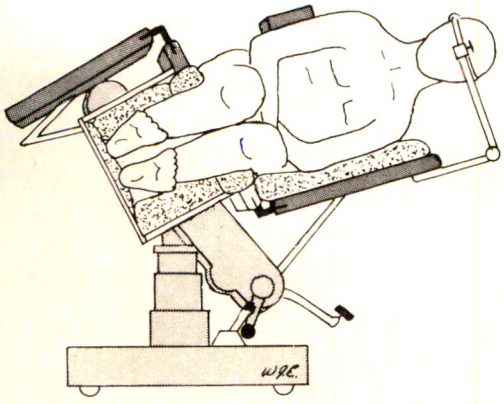

FIG 5. Patient brought down from left lateral sitting position (as shown in fig 2) to an almost complete left lateral horizontal position.

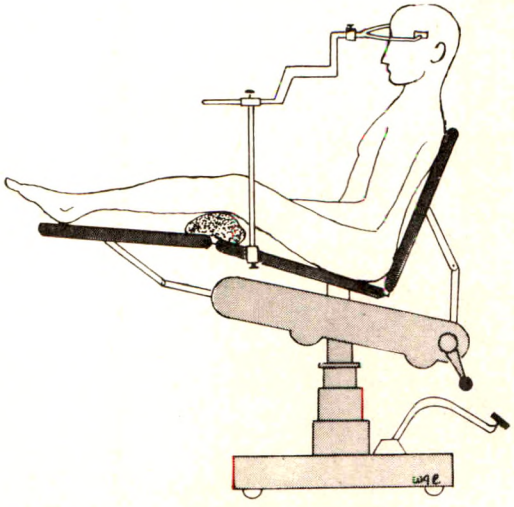

FIG 6. Conventional sitting position for operation in posterior fossa and cervical spine, as seen from left side of operating table.

can be completed in the lateral horizontal position or, if conditions permit, the head can be elevated again toward the vertical position. All these motions are achieved without disturbing the sterile conditions of the surgical field to which the surgeon retains, at all times, direct access, with full control of the wound.

The above description and illustrations refer to the American Sterilizer Company model 1080 operating table; not all other operating tables can be adjusted for this specific use.

COMMENT

For surgical procedures in the posterior fossa and the cervical spine, many neurosurgeons prefer to have the patient in the upright position. If arterial hypotension develops in a patient in the sitting position, one effective means of protecting the brain is to bring the patient to a recumbent position with the head lying on the same horizontal plane as that of the heart. However, when hypotension develops in a patient positioned in the conventional sitting position, as depicted in figure 6, lowering the level of the head can be achieved only by a backward and downward motion of the head, neck, and upper trunk. Thus positioned, the patient is supine, with the operative wound facing the floor. The fundamental conditions of surgical sterility are disrupted and the operative field becomes inaccessible to the surgeon. At best, all that can be accomplished is to protect the field with sterile towels until the situation is under control and the patient is either repositioned and redraped for continuation of surgery, or more commonly, the procedure is terminated and the wound closed.

In contrast, the lateral sitting position can be converted to the lateral horizontal position by simply manipulating the T-handle (fig 5). About 10° more of a head-down position can be gained if the back section of the table is lowered by the S-handle on the right side of the H-frame. This can be accomplished without hazard because the head is attached to the back piece where the neck, trunk, and head can be safely moved together. Further lowering of the head is probably unnecessary.

The position achieved in the lateral, horizontal position (fig 5) is essentially the same as that described by Mount.[3] If the patient's condition permits, operation can be resumed and completed in the lateral position. We have found that being able to move the patient safely and easily from upright to horizontal (and vice versa) is a most practical asset of the method, aimed at protecting the brain from potential ischemic effects of undesirable intraoperative arterial hypotension. Marshall[4] also has advocated the use of the lateral sitting position for the management of venous air embolism.

The left lateral horizontal position, as described above, is similar to that described by Durant's group[5] and evaluated by Oppenheimer and coworkers[6] for the treatment of venous air embolism. However, in patients with lateralized lesions, such as a cerebellopontine-angle tumor on the left

side, there may be advantage in reversing the patient's position on the operating table so that the left operative side is uppermost. Therefore, when the table is placed horizontally, the patient lies in the *right* lateral horizontal position. While this position has been shown in dogs to offer no advantage in the treatment of venous air embolism,[6] the ability to place the patient horizontal (right or left lateral) is of great therapeutic advantage in the management of arterial hypotension, whether secondary to air embolism or to other causes. This position also permits continued exposure of the operative site so that the surgical procedure will not be interrupted.

Over 300 neurosurgical procedures have been performed with the patients in the lateral sitting position. Approximately one-half of these procedures were suboccipital craniectomies and the remainder were cervical and upper thoracic laminectomies. No mortality or serious morbidity could be attributed to the use of this position. In nine instances where patients were placed in the lateral horizontal position for the treatment of hypotension, the arterial pressure was restored to adequate levels. Each operation was completed satisfactorily, with the patient maintained either in the lateral horizontal position or with the head subsequently raised 35 to 80° from the horizontal plane.

ACKNOWLEDGMENT

The authors gratefully acknowledge William J. Embro for preparing the drawings.

Inspired Air Temperature with Immersion Heater Humidifiers

KUNNATHU P. GEEVARGHESE, MB, BS, FRCP(C)*
J. ANTONIO ALDRETE, MD, MS†
TARANGINI C. PATEL, MB, BS‡
Louisville, Kentucky§

The temperature of aerosol mixture delivered from 2 types of immersion heater humidifiers was monitored at various sites along the delivery tube. As anticipated, the temperature of the humidified gas decreased as it moved distally from the aerosol generator to the T-adaptor in contact with patient's airway. The immersion heaters with fixed-temperature thermostatic control performed consistently, though most produced inhaled air temperatures higher than desired (>37° C). Immersion heaters with temperature reset features were in general unreliable and invariably gave higher inspired air temperatures with higher settings of the thermostat.

THE place of humidity in inhalation therapy and respiratory care is well established.[1-5] The use of heated humidifiers is common in postanesthesia recovery rooms and intensive care areas for patients with tracheostomy, prolonged endotracheal intubation, and those needing mask O_2 therapy, especially when there are secretion problems.

We employ the Puritan all-purpose nebulizers (model 126-056) with immersion heaters because they provide adequate water content to the inspired air in the form of humidity and aerosol droplets. These versatile units allow O_2 dilution with air. The immersion heater units are interchangeable and are available in 2 models: (1) model TR, with a temperature reset feature on the thermostatic control, and (2) model FT, with a fixed temperature thermostatic control.

From time to time we have noted that the inhaled O_2-air mixtures were too warm for patient comfort. This led us to monitor the temperature of the inspired air in 15 patients, using inhalation systems with heated humidifiers while employing mask or endotracheal tube for delivery of gases. Since the values in these preliminary observations varied from 23.3° to 42.2° C, and in 5 instances we had to discontinue treatment because of high temperatures, a more extensive and detailed study was undertaken.

MATERIAL AND METHODS

Fifteen immersion heaters, less than 1 year old and routinely serviced by the central sterilization unit, were studied. Fixed-temperature models were numbered FT 1 to 8 and temperature-reset models were numbered TR 9 to 16. An O_2 therapy system identical with those used in the clinical

situation was set up (fig 1). Temperature of the water bath was measured by an Hg (C) stem thermometer. The corrugated aerosol tubing of approximately 1.9 cm diameter* was 1.5 m long. The distal (patient) end of the tubing was connected with an aerosol T-adaptor† via a manifold thermometer assembly‡.

The expiratory limb of the T-adaptor was 15 cm long and the tracheostomy or endotracheal port received a 9.5 mm Portex clear plastic endotracheal tube. Thermistor telethermometer probes were installed via suitable airtight T-pieces at the outlet of the nebulizer and middle of the aerosol tubing. A third thermistor probe was located inside the T-adaptor at the patient end by inserting it through the expiratory limb. Thus the patient end T-adaptor had 2 temperature sensors to verify each other. The 3 thermistor probes were connected to channels 1 to 3 of a scanning telethermometer§. Temperatures were measured in Fahrenheit and converted to corresponding Celsius values.

The nebulizer was set at an O_2 inflow of 7 L/min and at 40% O_2 air dilution. All immersion FT heaters were tested individually. For each test, the whole equipment was started at room temperature, constantly maintained at 25.6° C and 45% relative humidity. Precautions were taken to ensure that the initial temperature of the system was at control level and that the tubing contained no water accumulation from prior use. Temperature readings were taken at 30 and 60 minutes from the start of the experiment. During this period, water accumulation in the tubing was prevented by gravitational drainage back into the nebulizer. In addition, the O_2 concentration was constantly monitored with an O_2 analyzer.

Three different groups of experiments were conducted with the TR heaters with the thermostatic control adjusted to 3 different settings: coldest, warmest, and median. Results were recorded and tabulated for each unit studied and with different thermostat settings (table).

RESULTS

As anticipated, the temperature of the gases from water bath to the patient end T-piece adaptor showed a gradual reduction. Whereas the inspired air temperatures were consistent and higher than desirable while using the FT model heater humidifiers

TABLE

Results of Inhalation System Temperature Observations Using Puritan FT and TR Model Immersion Heater Humidifiers in the Experimental System—All Observations Room Temperature 25.6° C, Relative Humidity 45%

Immersion heater model and thermostat setting	Temperature recording sites of system			
	Water in bath, °C Mean ± SD	Nebulizer outlet, °C Mean ± SD	Middle of tubing, °C Mean ± SD	T-piece adapter (inspired air), °C Mean ± SD
FT	58 ± 5	44 ± 2	39.6 ± 3	37.7 ± 3
TR—coldest	46 ± 15	36 ± 9	32 ± 8	30.5 ± 7.6
TR—warmest	64 ± 3	48 ± 2	43 ± 1	40 ± 1
TR—median	56 ± 8	43 ± 6	38.5 ± 5	35 ± 4.5

and the TR model with thermostat at the warmest possible setting, the TR models did not produce consistent values with lower settings of the thermostat.

Furthermore, the water temperature in the nebulizer peaked in 10 to 15 minutes; thereafter it remained steady as long as the water level remained within the "fill-to-level" and "refill" lines. With the nebulizer set for air dilution of 40%, the O_2 concentration recorded at the nebulizer outlet varied from 41 to 44%. It was also noted that if water was allowed to condense and accumulate in the aerosol tube without provision for gravitational drainage back into the nebulizer, the amount varied from 23 to 57 ml in 1 hour, depending on the temperature of the water in the nebulizer.

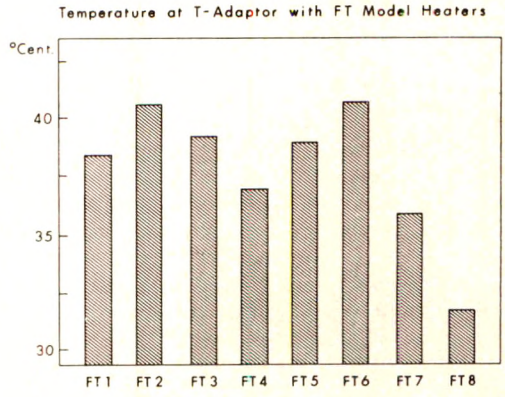

FIG 2. Temperature recorded at patient end T-adaptor with 8 FT model heaters.

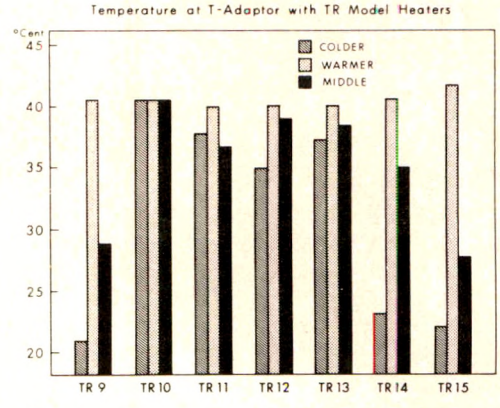

FIG 3. Temperature recorded at patient end T-adaptor with TR model heaters at 3 different thermostat settings.

DISCUSSION

Heated humidifiers raise the temperature of the water and are supposed to maintain it well above body temperature, to ensure that the gases passing downstream have temperatures around 37° C when they reach the trachea. This allows a considerable amount of heat and water to be administered to the patient. How well the tracheal mucosa tolerates heat is not well defined; prolonged breathing of air and O_2 at 37° C has been known to cause hyperpyrexia.[6] Hyperthermia has been reported in patients receiving IPPB using ventilators with heated humidifiers in the system where the temperature of inspired air varied from 29.4° to 41.7° C.[7]

Ideally, patients' air passages should not be exposed to temperatures above normal body temperature for long, since there are known deleterious effects on ciliary activity and possible direct thermal damage to the respiratory mucosa, but no harm should result if temperature of the inspired gases is maintained at 32° C. Air at this temperature, when 100% saturated, has a water content of 34 mg/L as compared to 44 mg/L in air at 37° C, a difference of only 10 mg. Preferably, the inspired air temperature should be monitored as close to the patient as possible. The Bennett MA-1 ventilator patient circuit incorporates an efficient cascade type thermostatically adjustable humidifier[8] with provision for monitoring the temperature of inspired gases downstream but, for practical reasons, not at the endotracheal connector.

Under clinically simulated conditions, except for the patient breathing air into the expiratory limb of the system, one finds that FT models performed more consistently, though in the majority of instances the inhaled air temperatures were higher than desired (fig 2). Thermostat settings were unreliable in most of the TR immersion heaters, which generally produced elevated inspired air temperatures with higher settings of the thermostat and were inconsistent with lower settings (fig 3).

Apparently the temperature of a heated aerosol reaching the patient in a system such as the one described depends on the following:

1. Type of breathing system—tracheostomy cannulas, endotracheal tubes, face masks, hoods, tents, etc.

2. The flow rate of gases.

3. The length, size, and thermal conductivity of aerosol delivery tubing.

4. The gradient between the heater and the ambient temperatures.

5. The level of liquid in the nebulizer container and rate of aerosol production.

The reliability and efficiency of the thermostat depends on its age, maintenance, cleaning, and sterilization. Sharp taps to the unit or dropping it on the floor can damage the thermostat. The greatest danger in the use of heated humidifiers is the possibility of thermostat failure and inhalation of excessively warm steam. If water is allowed to condense in the tubing and drain into the trachea instead of back into the humidifier, serious thermal damage to respiratory tract is possible.

An alternative to reduce excessive temperatures of the aerosol delivered to the patient is to elongate the aerosol tubing (in excess of 5 feet), though this becomes cumbersome, impractical, and wasteful. It is therefore recommended that close vigilance be kept over the actual temperature of the gases inhaled by patients.

In the above, we have studied the effects of 2 types of heater humidifiers on inspired air temperature with the air entrainment control for 40% O_2 only, since this is the commonly used level. The entrained room air at 40% O_2 setting might be expected to cool the aerosol mixture to a level below what might be expected with higher O_2 settings of 70 and 100%, since the proportion of entrained room air is less in these instances. These observations, with evaluation of some of the new units, will follow.

Clinical Investigation of a New Intravenous Anesthetic—Etoxadrol Hydrochloride (CL-1848C; U-37862A)

E. L. FREDERICKSON, MD*
DAVID E. LONGNECKER, MD†
GARY W. ALLEN, MD‡

Twenty-eight patients were anesthetized with etoxadrol as primary agent. The anesthesia produced was characterized by profound analgesia and amnesia, while pharyngeal and laryngeal reflexes, as well as swallowing and lid reflexes, remained active. Systolic, diastolic, and pulse pressure were slightly increased, with associated tachycardia and tachypnea. A dose of 0.75 mg/kg produced anesthesia for an average of 26 (14 to 53) minutes. Alternating nystagmus was present for several hours and associated with dreams and/or visions that were pleasing to most patients. Six patients, however, had unpleasant dreams for up to 24 hours. One patient given an excessive dose (4.65 mg/kg) was cataleptic, amnesic, and analgesic for 6 days. The occurrence of unpleasant dreams and aberrations in over 20% of the patients suggests that the drug probably has little usefulness in anesthesia. However, the extreme safety of the drug (an LD_{50} equal to some 20 to 40 times the ED_{50}) and the prolonged analgesia justified clinical testing. There was no evidence of metabolic or systemic organ system change from any of the clinical laboratory studies.

ETOXADROL hydrochloride, a newly developed anesthetic agent, has been found in animals to produce a state similar to that produced by ketamine but lasting 2 to 3 times longer. The compound is related to dexoxadrol, studied as an analgesic agent and with a potency similar to that of aspirin. However, analgesic doses of dexoxadrol produced mental confusion, hallucinations, and numbness of the arms and legs.[1] In etoxadrol, a much more potent agent than dexoxadrol, a phenyl group is replaced by an ethyl radical (figure). Chemically, it is unrelated to ketamine and other phencyclidine derivatives.

Extensive animal studies by Wilson and associates,[2-4] and by Hidalgo's group[5] have demonstrated that low doses of etoxadrol produce increased cardiac output with increased systolic, diastolic, and pulse pressures, associated with tachycardia, nystagmus, and salivation. The LD_{50} in many species was found to be 20 to 40 times the clinically effective dose. In monkeys, 2.5 mg/kg produced anesthesia adequate for endotracheal intubation and laparotomy, the anesthetic state usually lasting 25 to 30 minutes. The righting reflex was lost for an additional 90 minutes after the animal was returned to the cage.[5]

On the basis of prior work, Wilson's group[6] studied the drug in 13 healthy volunteers, reporting that a dose of 0.75 mg/kg produced a useful comatose state for 50 to

85 minutes in the 11 subjects given this dosage. A period of profound analgesia exceeded the period described as useful coma by varying amounts but was present in all subjects up to 2 hours or more. Each of the subjects experienced a major dream that seemed exceptionally real, the majority being described as pleasant or unusual experiences. In only one subject was there any evidence of a frightening situation; this occurred during the emergence phase and was thought by the investigators to be a "panic reaction." The EEG recorded from these subjects did not resemble that recorded during the use of any other drug, being characterized by an increase in the amplitude of an alpha activity, described as "juvenile alpha rhythm."

METHODS AND MATERIALS

The foregoing phase-I study in a comprehensive multidisciplinary, multiorgan evaluation of etoxadrol in normal human volunteers demonstrated the physiologic safety of this drug. We therefore decided to test etoxadrol in the clinical situation. After informed consent was obtained, the drug was administered to 14 patients by a single investigator. This initial clinical trial was later expanded to involve an additional 14 patients (table 1), using a similar clinical protocol.

RESULTS

The first 14 patients, anesthetized by one of us (ELF), underwent operations that were superficial in 6, urologic in 4, gynecologic in 2, orthopedic in 1, and thoracic in 1 (table 2). The anesthetic state produced by the drug was useful, and amnesia was complete for each patient. Relaxation was not good, and patients frequently made random movements of all their extremities, but the operative field remained quiet.

Induction doses ranged from 0.75 to 1 mg/kg IV over 20 to 40 seconds. Of the first 14 patients, only 2 stated they would not like to again have the same anesthetic for the same procedure, both complaining that the drug effect lasted too long, and one disliked the unpleasant dreams. Three of the 14 patients did not remember having

dreams; however, 2 of these patients obviously had been dreaming in the postoperative state, so perhaps their recall inability was related to poor communications. The rest of the patients had dreams that were recalled as pleasant, although frequently described as unusual. The most impressive characteristic of this drug was prolonged profound analgesia.

On the basis of this experience, the study was enlarged to a multiinstitutional study involving 4 other investigators. The protocol was defined in a more rigid manner, but still the investigator was given leeway to treat any complications that might occur and to give dosage up to a maximum of 1.5 mg/kg and other anesthetic agents if required for anesthesia. Premedication varied according to the individual preference of each investigator (table 3). No significant difference was noted in regard to drug interaction with any of the premedicants used.

The majority of surgical procedures were primarily superficial, but a considerable number were orthopedic, believed to entail significant postoperative pain. The drug was used only as an induction agent for the thoracotomy. It was noted that less etoxadrol was required in elderly patients, and that the degree of relaxation obtained was much greater than in younger patients.

Although there was a great deal of variation between patients in the depth and duration of anesthesia, there was a characteristic response to the induction dose, commonly 0.75 mg/kg, but on 4 occasions, 1 mg/kg was used electively. Three patients required 1.125 mg/kg before there was sufficient quietude to begin the operation (table 4). The response to this induction dose was initially sluggish speech and a blank stare with alternating horizontal and vertical nystagmus. Several patients stated that their body felt numb and that they felt as though they were dying. Facial motions, commonly of the lips and the tongue, were frequently associated with a slow rolling motion of the head. Vocalization continued during the procedure in 6/28 patients. Surgical stimulation did not appear to modify what appeared to be verbalization of dreams.

Respiratory rate was invariably increased, but on 2 occasions, a period of apnea that lasted approximately 10 seconds preceded the onset of tachypnea. The cardiovascular system appeared to be receiving increased sympathetic stimulation, as demonstrated by the increase in systolic, diastolic, and pulse pressures. Heart rate also increased, but not to an alarming degree. One patient had premature ventricular contractions with bigeminy, lasting for approximately 60 seconds. This was associated with surgical stimulation of the lower urinary tract. All patients appeared warm and none perspired, even when responding to surgical stimulation.

Conversation with the patients was frequently possible, although their speech was slow and anything beyond a single-word

answer appeared difficult. Muscle relaxation was evident only in the elderly patients, and more characteristic was a plasticity of the limbs with mild catatonic positioning. Airway maintenance was never a problem unless salivation was excessive. Swallowing was not uncommon during the course of the procedure. Elderly patients frequently had a relaxed airway and required some airway support shortly after induction.

In 9 patients whose temperature was monitored continually during the operative and postoperative periods, the increase in temperature never exceeded 1° C, but more significantly, there was no decrease in temperature greater than 1° C. This was deemed unusual, especially in light of the usual hypothermic response in patients having burn dressing changes and skin grafts.

It was impossible to prevent movement in 3 patients, even though the recommended maximum dose of the drug was given. For these procedures, the drug was considered unsatisfactory and other anesthetics were administered. All three of these patients were in the superficial surgery group and in the latter group of 14 patients. One had received morphine and atropine for premedication five hours before induction (case delayed) and scopolamine 0.2 mg IV seven minutes before induction. The other two received only atropine for premedication. Supplemental nitrous oxide only was needed for these last two patients for completion of their burn dressing change, but the former required morphine 4.0 mg IV as well as nitrous oxide so his ulnar neurolysis could be completed. The other 11 patients received nitrous oxide electively at the beginning of the procedure or because the maximum dose of etoxadrol had been used and a greater amount of anesthesia time was needed.

Adverse or threatening dreams were reported by 6/28 patients, all of whom had a prolonged period of recovery. Of these, 3 recalled periods of psychotic activity when they were totally unable to control their thoughts or actions. Only 7/28 patients stated that they had no dreams, and the dream content of the others most commonly included comments such as "floating," "puffy," and "out of this world." Relationship of dream content to past events in the patient's life was common. An individual who had been wounded in Vietnam had dreams of this unpleasant event. In contrast, most of the dreams were pleasant, relating to such things as childhood, trips away from home, military duty in Japan, or frequently just association with a pleasant scene.

Such mental aberrations frequently persisted up to 18 to 24 hours. However, they were voluntarily controlled by most of the patients and could be reinstituted if the patient closed his eyes. In one patient (who had inadvertently been given 4.65 mg/kg) this effect lasted for 6 days.

One of the most profound results of etoxadrol was the production of an analgesic state characterized by an awareness of pain when called to the patient's attention, but frequently accompanied by the statement "It doesn't bother me." Postoperative analgesic agents were rarely needed, and stimulation of donor sites of skin graft elicited little or no response, even though the patient was responding rationally.

Of the 28 patients, 5 vomited without nausea following postoperative fluid intake. One patient, who had a previous history of nausea and vomiting after other anesthetic procedures, continued with nausea and vomiting for 48 hours after anesthesia with this drug.

Postoperative clinical laboratory studies showed no significant changes in hemoglobin, red or white blood count, hematocrit, creatinine, urinalysis, SGOT, LDH, alkaline phosphatase, or total blood proteins. Two of the patients had mildly elevated BUN, both before and after operation, and 4 had a minimally elevated SGOT, both before and after operation.

DISCUSSION

As the response pattern to etoxadrol is new to anesthesia, comparison in this study is primarily based on subjective comments and opinions of the clinical response of patients. The drug does produce a comatose state characterized by CNS, cardiovascular, and respiratory stimulation.

In attempting to group this compound with other anesthetic agents, we are obliged to compare it with the group classified by Winters and associates[7] as demonstrating all states of electrical activity in the EEG up to generalized seizures. This group includes the phencyclidine compounds, gamma hydroxybutyrate, alpha chloralose, trichloroethylene, and enflurane, a variety of compounds that appear to have no chemical relationship. However, they all produce a state of CNS depression and analgesia frequently associated with hallucinatory and

epileptoid components in primates, including man. Chen[8] states that the arylcycloalkylamines (phencyclidine, cyclohexamine, and ketamine) and the 1,3 dioxolanes (dexoxadrol and etoxadrol) are "sympathomimetic anesthetics," classified as anesthetic agents only because they eliminate the response to surgical stimuli in a reversible manner. The obvious lack of inhibition, EEG changes, and behavioral changes seen in animals, as well as the production of profound analgesia, imply that the action of these drugs on the CNS is widely ramified, either by direct action on receptor sites or indirectly by modification of neurotransmitter synthesis, metabolism, release, or uptake.

Future study of these drugs may elucidate the mechanism of CNS changes. Current studies on various monoamines within the CNS demonstrate that profound behavioral effects and sleep are produced by changes in both content and turnover rate of these amines. It is evident from these and other studies that serotonin, norepinephrine, and dopamine are all of significance in terms of CNS function.[9]

We have found a significant difference in brain concentration of these amines during and after the administration of thiopental, ketamine, and etoxadrol. The apparent rate of synthesis of brain serotonin was reduced to 50 to 60% of control levels 4 hours after administration of both ketamine and etoxadrol. These drugs also produced increases in the apparent rate of brain dopamine synthesis, which reached as much as 200% of control 6 hours after administration. In contrast to this, thiopental caused only a marginal decrease in the apparent synthesis rate of brain serotonin and a 30% decrease in apparent synthesis rate of dopamine in rats.[10]

The production and incidence of dreams during or after anesthesia, characteristic of many anesthetic agents, has received the attention of many investigators, especially with ketamine.[11] Brice and colleagues[12] and Crawford's group[13] demonstrated a high incidence of dreaming during thiopental-N_2O-relaxant anesthesia. The mental aberrations observed in our study do not necessarily relate to awareness during operation, although the surgical procedure may stimulate the delusion. One of our patients had a lymph node removed from the anterior cervical chain just cephalad to the thyroid gland. After recovery, he claimed he had watched the operation from a corner of the operating room, finding it not an unpleasant experience. Memory of actual events during the surgical procedure could not be elicited from any of our patients.

The high incidence of unpleasant dreams or psychotic experience has prevented further clinical investigation of etoxadrol as an anesthetic agent. However, continued animal studies relating to both its analgesic action and CNS effects have continued.[14] It is hoped that future studies will further our understanding of the mechanism of action of anesthetic agents and of analgesia, for the increased safety and efficacy of anesthesia.

Endobronchial Intubation for Intraoperative Protection of a Single Functioning Lung: A Case Report

JAY B. BRODSKY, MD*
MICHAEL D. ABRAMAWITZ, MB†
MARY P. MEHREZ, MD‡

ELECTIVE endobronchial intubation is usual for intrathoracic surgery. A case is presented demonstrating a role for endobronchial anesthesia in situations when assured access to a single lung is necessary.

A 51-year-old woman was admitted with signs and symptoms of acute spinal-cord compression. Five months earlier, carcinoma of the right lung with lymph-node involvement had been diagnosed, for which she was treated with radiation (6000 r) to the trachea, carina, and paratracheal lymph nodes. In the 2 months before admission, the patient experienced increasing thoracic back pain associated with dyspnea, developed a productive cough, and was given antibiotics for multiple right-lung abscesses noted on chest x-ray.

On admission, gas myelography demonstrated collapse and destruction of the 6th thoracic vertebral body, associated with an epidural soft-tissue mass which compressed the spinal cord. Emergency decompressive surgery was indicated. A preoperative roentgenogram showed a large, left paratracheal lymph node compressing the trachea, and a completely opaque right hemithorax. Breath sounds were absent on the right but the left lung was clear.

An arterial blood-gas sample, drawn while the patient breathed room air, showed Pao_2 71 torr, $Paco_2$ 32 torr, pH 7.47, total CO_2 23 mM/L, and base excess +1 mEq/L. Thoracocentesis yielded 500 ml of serosanguinous fluid, but the procedure was discontinued when the patient experienced pleuritic pain. Postthoracocentesis chest x-ray showed no reduction in the right pleural effusion or reexpansion of the collapsed right lung (fig 1).

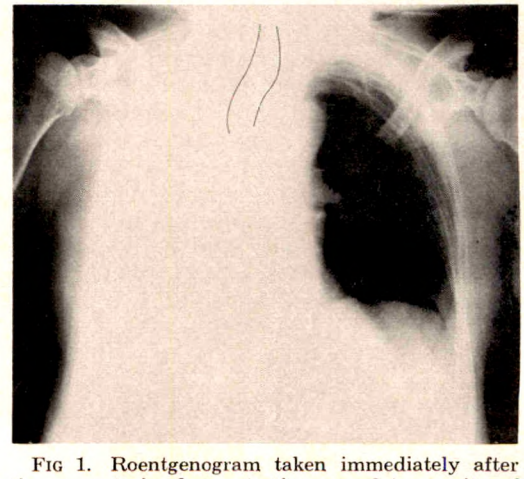

FIG 1. Roentgenogram taken immediately after thoracocentesis, demonstrating complete opacity of right lung. Dark lines outline position of trachea as determined by bright-light transillumination of original x-ray.

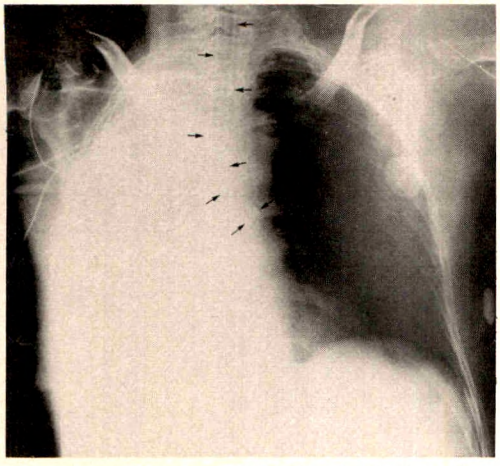

FIG 2. Roentgenogram following intubation, demonstrating (arrows) that left endobronchial tube has bypassed site of potential obstruction, permitting patient to be placed prone. Note also some aeration of right lung, due to positive-pressure ventilation.

Anesthetic induction consisted of preoxygenation, followed by a sleep dose of sodium thiopental, d-tubocurarine to prevent fasciculations, and succinylcholine to facilitate intubation. The larynx was sprayed with 4% lidocaine, and a 35-French Carlens left double-lumen endobronchial tube was passed (fig 2).

The patient, placed in the prone position, underwent a 2-hour decompressive thoracic (T5-7) laminectomy under N_2O-O_2-halothane anesthesia, with increments of d-tubocurarine, without complications. Ventilation was controlled and intraoperative blood-gas samples demonstrated satisfactory gas exchange.

After postoperative return to the supine position, the patient received atropine and neostigmine and was extubated in the operating room. In the recovery room, she breathed 40% O_2 via a heated nebulizer without respiratory difficulty and was returned to her room 4 hours postoperatively.

The patient's immediate postoperative course was satisfactory and she showed signs of neurologic improvement, but the right pleural effusion persisted and required frequent drainage. Eventually nitrogen mustard successfully prevented reaccumulation of the effusion, and the right lung was partially reexpanded. However, the patient developed antibiotic-resistant pneumonia and expired 7 weeks postoperatively from respiratory failure.

DISCUSSION

In 1931, Gale and Waters[1] suggested the use of single-lumen cuffed tubes for closed endobronchial anesthesia during thoracic surgery. Carlens,[2] in 1949, introduced the double-lumen endobronchial catheter into clinical practice. These technics are usually employed to prevent contralateral spread of material from diseased to healthy lungs and to provide a selectively collapsed lung when necessary during intrathoracic surgery.[3-5]

Our patient had a single functioning lung. The potential hazard of obstruction of the main bronchus to that lung from extrinsic compression by enlarged paratracheal lymph nodes was revealed by the preoperative chest x-ray. Placing the patient prone for the surgical operation would have made access to her functioning left lung difficult in the event of intraoperative upper-airway obstruction. Elective endobronchial intubation bypassing the site of possible airway obstruction was demonstrated radiologically prior to turning the patient to the prone position.

In addition to assuring access to the left lung, the double-lumen Carlens tube isolated that lung from the secretions and tumor cells of the opposite lung. Any double-lumen left endobronchial tube would have been equally appropriate. Intraoperative ventilation of both lungs demonstrated some aeration of the right lung during controlled positive-pressure ventilation (fig 2).

Intraoperative endobronchial intubation should be considered in emergency operations with potential compromise of a single functioning lung, although this technic is not without hazards, since trauma to the airway from difficult intubation can potentiate obstruction, especially during the immediate postextubation period. Patients should be carefully observed in the recovery room or intensive care unit following extubation, and means for establishing an open airway should be available by the bedside.

ACKNOWLEDGMENT

The patient's case record is filed at Beth Israel Hospital, Boston.

THE EFFECT OF PROLONGED BREATHING OF O_2 IN HIGH CONCENTRATION ON THE RESPIRATORY SYSTEM: EXPERIMENTAL INVESTIGATIONS. Although no attempt was made to extrapolate results from dogs to man, statistically impressive data were derived from a study of 17 dogs (7.5 to 30 kg) investigated to answer 3 major questions: (1) What is the effect (in dogs) of breathing 100% O_2 at 1 atm (600 torr) for up to 48 hours? (2) Can controlled respiration alter the action of prolonged O_2 breathing in high concentrations? (3) What, if any, pulmonary damage results from breathing? Assessment of the cardiorespiratory system was based on an analysis of indices determining (1) respiratory mechanics, (2) ventilation:perfusion relationships, (3) gas-exchange values, (4) O_2 transport and utilization in tissues, (5) morphologic lung changes. The author concludes: (1) All dogs showed pulmonary damage after 30 hours, changes beginning by the 12th hour and appearing during spontaneous as well as mechanical O_2 ventilation. (2) Respiratory rate, A: a ratio, and pulmonary shunting increased; lung compliance decreased; CO_2 excretion was impaired. (3) Pulmonary morphology showed extensive atelectasis and exudative reaction. (4) Mechanical respiration increased the O_2-induced damage. (5) Long-term quiet breathing of O_2 also disturbed the $\dot{V}/\dot{Q}$ ratio. (6) If long-term high concentrations of O_2 must be administered, Pa_{O_2} should not be permitted to exceed 100 torr, as dysplasia bronchopulmonalis is likely to result even earlier in man than in dogs. *(Szreter. Anaesth Resusc Intensive Ther 1:305-324, 1973.)*

Prolonged Neuromuscular Blockade with Pancuronium in the Presence of Acute Renal Failure: A Case Report

DWIGHT G. GEHA, MD*
CASEY D. BLITT, MD†
B. J. MOON, MD‡
Tucson, Arizona§

Prolongation of neuromuscular block following pancuronium administration to anephric patients has been reported. A patient is described whose postoperative course after resection of gangrenous bowel was complicated by acute renal failure and prolonged neuromuscular blockade. A large intraoperative dose of pancuronium was administered without monitoring neuromuscular transmission with a peripheral nerve stimulator.

The course was further complicated by administration of gentamicin, an antibiotic known to potentiate neuromuscular blocking drugs. Complete return of neuromuscular transmission occurred 60 hours after administration of the last dose of pancuronium and subsequent to peritoneal dialysis.

After rapid distribution from plasma, pancuronium, like curare, is eliminated by the renal pathway. The absence of renal excretion considerably increases the duration of action of curare when given in high doses. It has been suggested that doses of pancuronium greater than 3.6 mg/sq m or multiple doses would result in prolonged neuromuscular block in patients without renal function. The case reported illustrates the importance of monitoring neuromuscular transmission during administration of pancuronium in the presence of renal insufficiency to avoid this complication.

PROLONGED neuromuscular blockade following pancuronium administration has been reported (1) in a healthy young woman,[1] (2) in association with the antibiotic polymyxin-B,[2] and (3) in an anephric patient with biliary obstruction and evidence of hepatocellular dysfunction.[3] Adler and Pilon[4] found that anephric cats required twice as long as normal animals for return of neuromuscular transmission following pancuronium. In a clinical study, Miller's group[5] found that single doses of 1.8 to 5.5 mg of pancuronium given to patients in renal failure resulted in a neuromuscular block lasting 20 to 40 minutes longer than in patients with normal renal function.

This report describes a patient who received a large intraoperative dose (11.8 mg/sq m body surface area) of pancuronium and whose subsequent postoperative course was complicated by acute renal failure and prolonged neuromuscular blockade. In addition, the patient received 2 doses of gentamicin, an antibiotic known to be associated with clinical neuromuscular block.[6,7] Of major importance, however, was the failure to monitor neuromuscular transmission

with a peripheral nerve stimulator. If the dose of pancuronium had been "titrated" according to the twitch response, an excessive dose would not have been given.

CASE REPORT

A 63-year-old Caucasian woman was admitted to the emergency room comatose, dyspneic, cyanotic, and in shock. Systolic blood pressure was 70 torr, heart rate 120 bpm, and rectal temperature 39.6 C. The abdomen was markedly distended. Initial resuscitative efforts included administration of O_2, 2 L of balanced salt solution, dopamine by continuous infusion, hydrocortisone sodium succinate (1 gm), gentamicin (80 mg), sodium cephalothin (2 gm), and digitalis.

History revealed 48 hours of nausea, vomiting, abdominal pain, intermittent hematochezia, several diarrheal stools, and absence of urination. Past history included cobalt irradiation for a transitional-cell carcinoma of the bladder 2 years previously. An intravenous pyelogram at that time indicated a nonfunctioning right kidney. In addition, she had a history of asthma treated with 40 units of ACTH monthly and self-administered aminophylline.

Despite initial improvement, the patient became increasingly tachypneic. The trachea was intubated and mechanical ventilation instituted. Pancuronium bromide (6 mg) IV was given to achieve a satisfactory ventilatory pattern and an acceptable peak inspiratory pressure. A diagnosis of septic shock due to large-bowel obstruction and necrosis was made and the patient was taken to the operating room.

Anesthesia was induced and maintained with N_2O-O_2 and fentanyl. At the time of induction, gross movements indicated recovery from the previous neuromuscular blockade, and pancuronium (4 mg) was given. Fentanyl (0.25 mg) and additional pancuronium (14 mg) were administered during a 6-hour surgical procedure consisting of lysis of adhesions, colon resection, and colostomy. The total dose of pancuronium, including the 6 mg given preoperatively, was 24 mg. No peripheral-nerve stimulator was used. Fluids administered totaled 5500 ml of crystalloid, and urine output was 320 ml. At the conclusion of the operative procedure, the patient was taken to the ICU with the endotracheal tube in place and mechanically ventilated with a Bennet MA-I respirator. No attempt was made to antagonize the neuromuscular block. The patient was unresponsive, but vital signs were stable, with blood pressure 120/90 torr, heart rate 100 bpm, CVP 15 cm H_2O, and rectal temperature 36.6 C. Arterial blood-gas values on F_{IO_2} 0.5 showed a Pa_{O_2} of 96 torr, Pa_{CO_2} 33 torr, pH 7.40, and HCO_3 21 mEq/L. Total protein was 5.1 mg/100 ml with albumin of 2.7 mg/100 ml. During the first 3 postoperative days, electrolytes were Na^+ 142 to 148 mEq/L, Cl^- 92 to 100 mEq/L, K^+ 3.8 to 5.1 mEq/L, and CO_2 20 to 25 mEq/L. BUN increased from 50 mg/100 ml to 90 mg/100 ml and creatinine from 3 mg/100 ml to 7.6 mg/100 ml.

During the first 12 hours in the ICU, urine output remained low, totaling less than 600 ml, in spite of crystalloid fluids, 5% purified protein fraction (Plasmanate®), and repeated doses of furosemide (Lasix®). Serum and urine osmolality were 303 mOsm and 291 mOsm, respectively, and urine Na 51 mEq/L, compatible with acute renal failure. The patient continued to be unresponsive.

Fourteen hours after the last dose of pancuronium, and nearly 20 hours after the initial dose, a peripheral nerve stimulator (Burroughs-Wellcome, 50 Hz) applied in the area of the ulnar nerve at the wrist via subcutaneous needle electrodes elicited no twitch and no response to tetanic stimulation.

On the morning of the 2nd postoperative day and 37 hours after the last dose of pancuronium, a slight twitch, rapid fade in response to 50 Hz stimulation and post-tetanic facilitation were observed. Several hours later, the patient received a second dose of gentamicin (80 mg) IM and an hour later the twitch response was absent. Later in the afternoon, peritoneal dialysis was instituted, with 11 dialysis runs by the following morning. At that time, 60 hours after the last pancuronium dose, a strong twitch, sustained tetanus, and absence of post-tetanic facilitation were observed. The patient died on the 13th postoperative day from renal failure, gram-negative sepsis, and septic shock.

DISCUSSION

The cessation of effect of neuromuscular blocking drugs other than succinylcholine depends upon redistribution and excretion, mainly by urinary filtration.[8] Following IV administration, plasma concentration reaches an initial peak and then falls rapidly in

an exponential manner. Using isotope-labeled compounds, it has been shown that the drugs will be localized in muscle, especially concentrated at the junctional area, but the highest tissue concentrations are present in liver, spleen, and kidney.[8]

Recently, Gibaldi and coworkers[9] have described a pharmacokinetic, multicompartmental model for the distribution and elimination of d-tubocurarine (dTc) in man, based upon previously reported data on plasma and extracellular fluid. It further illustrates that there is a disproportionate increase in duration of effect of dTc with large doses. Using this model, Gibaldi's group have shown that absence of renal excretion increases the duration of action of curare only slightly in the low-dose range but considerably in the high-dose range.[10] They conclude that renal failure will primarily affect the duration of action of large single and multiple doses of d-tubocurarine.

The elimination of pancuronium in man has been reported by Agoston and associates.[11] A single IV injection of pancuronium disappears from plasma in 3 phases with a half-life of less than 5 minutes, 7 to 13 minutes, and 108 to 147 minutes, respectively. Detectable levels are still present after 4 hours. At 30 hours, approximately 40% of the injected dose was recovered in the urine and 10% in bile. A small amount of this was accounted for by 1 metabolite and the remainder was unchanged pancuronium. Thus it appears that the distribution and elimination of pancuronium and dTc are similar.

Miller's group[5] found that 1.8 to 5.5 mg of pancuronium resulted in a duration of neuromuscular block 20 to 40 minutes longer in anephric patients than in patients with normal renal function. Assuming that pancuronium is 5 to 8 times more potent than dTc, his results were comparable to those predicted by the computer model of Gibaldi for dTc in patients with renal failure. Based on this comparison, Miller suggested that doses of pancuronium greater than 3.6 mg/sq m or multiple doses would result in prolonged neuromuscular block in patients without renal function.

Renal excretion is the primary pathway of elimination of both dTc and pancuronium. In the absence of renal function, the biliary elimination of dTc is increased fourfold.[12] Whether this occurs with pancuronium is not known. Thus the dose of pancuronium administered in the presence of decreased or absent renal function must be carefully controlled, especially if more than 1 increment is given. The degree of neuromuscular block present and the amount of neuromuscular blocking-drug required can be adequately assessed only by a peripheral nerve stimulator.

Unrelenting Hypotension Associated with an Acute Abdomen in a Comatose Hemophiliac Child: A Case Report

ROBERT W. VAUGHAN, MD*
SUSAN L. WILSON, MD†
LAWRENCE S. WALDBAUM, MD‡
St. Louis, Missouri§

A comatose 4-year-old hemophiliac presented with an acute abdomen; subsequently he developed unrelenting hypotension. An immediate exploratory laparotomy was required, without time for determining baseline factor VIII (AHF) levels. Despite hypotension and hemorrhage, vigorous intraoperative fluid volume replacement and the administration of fresh frozen plasma and AHF concentrates brought a successful conclusion.

SUCCESSFUL operative management of hemophiliacs requires a team effort by anesthesiologist, surgeon, and hematologist. Pechet and Glaser[1] reviewed the problems encountered in the surgical treatment of such patients. Although preoperative assessment of factor-VIII (antihemophilic globulin, AHF) plasma levels is desirable to evaluate the efficacy of therapy,[2] one may be forced to proceed with anesthesia and operation without this initial laboratory guide. In such an emergency, readily available AHF concentrates and fresh frozen plasma are mandatory. This case report emphasizes numerous problems one can encounter in a hemophiliac presenting for emergency surgery.

REPORT OF A CASE

An obese 4-year-old Negro boy, weighing 29 kg, had been active until 5 days prior to admission, when he developed vomiting, frontal headache, and was treated at another hospital with IM penicillin. Past history was significant in that the patient was a hemophiliac, a diagnosis made at 8 months of age, when he suffered an intracranial hemorrhage. During that hospitalization, a ventriculoperitoneal (VP) shunt was made for communicating hydrocephalus. His progress over the ensuing 3½ years was marked by periodic emergency room and clinic visits for spontaneous bleeding episodes.

Four days before admission to our hospital, the frontal headaches progressed to grand mal seizures. His overall neurologic condition worsened, and he was transferred to our hospital. On admission to the pediatric service, his state of consciousness fluctuated between lethargy and combativeness. Although no history of trauma was obtainable, this possibility could not be excluded because of his disoriented, uncooperative mental status. Vital signs in the emergency room revealed a blood pressure of 70/40 torr, pulse rate between 170 to 200 bpm, and rectal temperature of 38.5 C.

Significant physical findings included marked abdominal distention, with a palpable left upper-quadrant mass, fullness of

the right temporal area over the VP shunt, massive swelling of the right upper arm at the previous IM injection site with faintly perceptible distal pulses, and well-healed scars from 7 previous peripheral cutdowns. Pertinent abnormal laboratory findings included a hematocrit of 22%, serum K^+ 3 mEq/L, and chest radiograph revealing scattered peripheral infiltrates. Although a radiograph of the abdomen confirmed the huge abdominal mass, the position of the catheter tip for the VP shunt could not be definitively located.

The surgical service was consulted for placement of an IV cutdown in the left forearm; 200 ml of lactated Ringer's solution with 5% dextrose was given, leading to an increase in systolic pressure (110 torr). Nevertheless, while still in the emergency room, the patient became more lethargic, again developed hypotension (50 torr systolic), and suffered a respiratory arrest. A 4 mm ID uncuffed endotracheal tube was placed. Two units of non-type-specific O-negative packed erythrocytes were transfused, plus an additional 1000 ml of crystalloid solution (equally divided between normal saline [NS] and lactated Ringer's [RL]), without an increase in blood pressure. As the abdominal girth continued to increase, the carotid pulses became barely palpable. The patient was rapidly transferred to the operating room.

Upon presentation for immediate exploratory laparotomy, systolic blood pressure was 50 torr, carotid pulses (rate = 160 - 180) were faintly palpable, and breath sounds were absent to auscultation of the left hemithorax. The endotracheal tube was withdrawn until breath sounds were bilaterally equal; however, because of copious secretions and an inability to adequately suction through the small tube, optimal ventilation was impossible. A 5.5 mm ID uncuffed endotracheal tube was rapidly placed and its position verified by auscultation. Subsequently, copious amounts of brownish-yellow material could be suctioned from the airway.

While ventilation was controlled with 100% O_2, d-tubocurarine was given IV (1 mg increments) to produce muscle relaxation, with N_2O added to a maximum of 50% concentration for anesthesia. As long as blood and electrolyte fluids were continuously administered by syringe, the systolic blood pressure (using a cuff on the left leg) could be maintained at 50 to 60 torr. An unsuccessful attempt was made to place a Doppler probe near the popliteal artery. Neither upper extremity could be used for monitoring blood pressure.

Certainly, a central venous pressure (CVP) determination could have helped gauge the rate of fluid and blood administration. Several considerations made us reluctant to place this monitor. For example, the only route available for the catheter was a second left upper-extremity cutdown or percutaneous subclavian or internal jugular puncture. In this hemophiliac, the safety of both options seemed questionable. Furthermore, we were hesitant to rely on whatever reading we obtained without radiographic verification of catheter tip placement.

Accordingly, placement of a CVP monitor was deferred. Since the preoperative diagnosis was intraabdominal hemorrhage, the surgeons proceeded with an immediate exploratory laparotomy. Total fluid volume administered during the course of the unrelenting preoperative hypotension included 2 units each of whole blood, packed erythrocytes, fresh frozen plasma, and electrolyte fluids (RL and NS), and 3 ml/kg of AHF concentrate.

A transverse abdominal incision down to the peritoneum resulted in profuse venous bleeding. No free blood was visible through the peritoneum. All fluid and blood administration was discontinued. Only when the peritoneum was opened was the extent of the abdominal mass appreciated. It extended from behind the stomach into the left upper quadrant and almost filled the abdominal cavity. Marked venous engorgement was also demonstrable in the vessels of the lower abdomen. Bloody fluid (900 to 1200 ml) was drained from the cyst. Progressively, blood pressure rose from 60 torr systolic to 120/70 torr. Exploration of the abdomen revealed no other bleeding sites. The pancreatic pseudocyst was marsupialized to the posterior stomach wall and the abdomen was closed without incident.

Neuromuscular block was antagonized with the IV administration of neostigmine (0.07 mg/kg) while simultaneously blocking the muscarinic receptors with IV atropine (0.02 mg/kg). With endotracheal tube in place, the patient was transferred with continuous O_2 administration to the pediatric intensive care unit. Upon arrival, frothy pink fluid was suctioned from the airway. Hematocrit was 66%; chest radiograph

was consistent with the diagnosis of pulmonary edema, aspiration pneumonitis, and/or "shock lung." Subsequent therapy included controlled mechanical ventilation, phlebotomy (700 ml) to a hematocrit of 40%, and furosemide (1 mg/kg), repeated twice (1 hour apart). Mechanical ventilation was maintained for 48 hours; weaning and extubation were without incident. The remaining portion of the hospital course was uneventful, with factor-VIII levels maintained above 30% during the postoperative period.

DISCUSSION

This patient's persistent hypotension was treated vigorously with volume replacement. In face of an enlarging abdominal mass with hypotension in a hemophiliac, the most likely preoperative diagnoses were either a ruptured spleen with intraabdominal hemorrhage or bleeding from an intraabdominal complication of the VP shunt. Ideally, we would have awaited AHF levels before proceeding with operation. However, the patient's cardiovascular status forced operation without adequate preparation.

Iatrogenic fluid overload resulted from the mistaken assumption of intraabdominal blood loss. Nevertheless, in retrospect, the volume therapy seems appropriate in view of the hypotension associated with increasing abdominal girth. Cardiac filling depended upon our continuous fluid infusion by way of the superior vena cava; almost complete inferior vena cava obstruction prevented venous return. With surgical evacuation of the pancreatic pseudocyst, venous return from the inferior vena cava resumed and blood pressure promptly returned toward normal. With reentry of the administered volume into the effective circulating blood volume and discontinuance of controlled mechanical ventilation, pulmonary edema ensued.

Several possibilities exist to explain this edema. The most obvious is volume overload; however, underlying aspiration pneumonitis with damage to the alveolar epithelium could not be excluded. A significant probability exists that regurgitation with aspiration occurred before the patient's arrival in the operating room. Treatment of this possibility included controlled mechanical ventilation with supplemental O_2, but without corticosteroids or antibiotics. Tillotson and Finland[3] have shown that the prophylactic use of antibiotics following aspiration may be unwarranted, especially since resistant superinfection is likely after administration of antibacterial agents. Recently, Downs and associates[4] showed in dogs that the effects of hydrochloric acid-induced aspiration pneumonitis were unaltered by low, high, or multiple doses of methylprednisolone.

Malfunction of the venous portion of the VP shunt, with subsequent compression of the catheter tip, was judged responsible for the right temporal fullness causing increased intracranial pressure (ICP). Prior to admission, this led to fluctuating levels of consciousness with seizures. In addition, increased ICP would be particularly important as an etiologic factor in producing pulmonary edema. The increased ICP occurred prior to the overload of blood and balanced salt solutions.

Injuries to the central nervous system may be associated with the development of acute pulmonary edema even in the absence of overt left ventricular disease.[5-8] Cameron and De[5] produced edema in dogs by injecting fibrin into the 4th ventricle. Sarnoff and Sarnoff[6] confirmed these observations and showed that sympathectomy ameliorated the pulmonary liquid accumulation; hypothalamic lesions (hemorrhage, infectious, neoplastic, or traumatic) may be the critical factor by causing adrenergic overactivity. This produces shifts in blood from the systemic to the pulmonary circulation, loss of left ventricular compliance, with left atrial and pulmonary capillary hypertension and subsequent edema.[7] Indeed, a variety of sympatholytic, antiepinephrine, or general anesthetic agents appear to relieve experimental neurogenic pulmonary edema.[8]

Grosfeld's group[9] reported a 24% incidence of intraabdominal complications (perforation of the colon and bladder, intraabdominal CSF cyst, and intestinal obstruction due to volvulus) following VP shunt. Certainly these reported intraabdominal complications could not be ruled out preoperatively. On the other hand, our diagnoses were further complicated by an underlying hematologic disorder.

The sex-linked genetic deficiency in hemophilia is related to reduced AHF activity.[2] With most methods, AHF levels in the normal population vary between 50 and 200% but are constant in each individual if blood is drawn under the same circumstances. In patients afflicted with severe hemophilia, the AHF level is almost invariably below 2%, but it may be as high as 20% in mild cases.[1] Most investigators agree

that an AHF level of at least 30% of normal must be achieved during operation, and that levels not lower than 15 to 30% be maintained constantly during the healing process.[10]

Our pediatric patient presented a problem in repletion of factor VIII. The requirement for very large amounts of fresh frozen plasma (FFP) during surgical management tends to induce severe hypervolemia. Originally, FFP was administered to correct the supposed hypovolemia while simultaneously giving AHF. However, cryoprecipitate fractions obtained from FFP and allowed to thaw slowly may yield 50% of the original factor VIII. It is relatively easy to prepare, is obtainable from most blood banks, and obviates the potential hypervolemia from FFP. In our patient, postoperative AHF requirements were met with these concentrates.

Although this case presented a myriad of problems, encouraging results can now be obtained with increasing experience and the availability of fresh frozen plasma and AHF concentrates. With close cooperation among the anesthesiologist, surgeon, and blood bank, life-saving procedures can now be undertaken for acute or elective surgical procedures in hemophiliacs. Nevertheless, one must be prepared to carefully monitor AHF levels and to maintain adequate dietary and metabolic care during the generally protracted postoperative course.

An Unusual Complication of Lumbosacral Plexus Block: A Case Report

STANLEY MURAVCHICK, PhD, MD*
WILLIAM D. OWENS, MD†
St. Louis, Missouri‡

Lumbosacral plexus block is a valuable anesthetic technic in the hands of an experienced anesthesiologist. However, as illustrated by this case report, anesthetic dosage must be selected with great care, and patients unable to describe paresthesias should be excluded from use of this procedure.

THIS report describes an unusual complication of an attempt to provide regional anesthesia by means of lumbosacral plexus block in an aged and debilitated patient.

CASE REPORT

An 89-year-old woman with an extensive history of systemic vascular disease was admitted to the hospital for evaluation of pain, cellulitis, and ulcerations of the right foot. A femoral popliteal arterial bypass procedure had been performed on the right leg 4 years earlier for arterial insufficiency. In addition, the patient had a history of arterial hypertension, coronary artery disease, and diabetes mellitus treated with oral hypoglycemic agents. An episode of acute congestive heart failure was reported, but cardiovascular status was now controlled by continuing therapy with furosemide.

Physical examination revealed a thin woman, appearing of stated age, with apparently diminished hearing acuity. Vital signs at admission were recorded as weight, 50 kg; blood pressure, 200/80 torr; pulse irregular and approximately 80 bpm; respiration, 16/min. Auscultation of the chest revealed a few basilar rales. No cardiac murmur was described. Cellulitis and ulceration of the dorsal and medial surfaces of the right foot were noted. The rest of the examination was noncontributory.

On the 3rd day of hospitalization, after evaluation of ECG, blood-chemistry studies, and arteriography, the patient had a right peroneal artery graft performed under spinal anesthesia. The graft subsequently failed, and an above-the-knee amputation of the leg was scheduled for the 7th hospital day. The patient was evaluated preoperatively as being of ASA physical status IV, and the anesthetic plan included a right lumbosacral plexus block without premedication.

The evening before operation, the patient became very confused; after consideration of physical findings, arterial blood-gas evaluation, and diagnostic blood-chemistry studies, it was felt that the patient had become toxic from gangrenous changes in her ischemic extremity. Plans for operation the following morning were unchanged.

The patient arrived at the operating room disoriented and intermittently somnolent. An IV fluid infusion was started and a

Paper received: 7/28/75
Accepted for publication: 9/15/75

blood-pressure cuff and ECG leads were applied. Arterial blood pressure was 180/60 torr, pulse rate 80 bpm, and respirations 14/min. After left lateral decubitus positioning, preparation of the skin, and draping, the necessary anatomic landmarks of L_3-L_4 interspace and posterosuperior iliac spine were easily identified. At the point of intersection of the lines drawn across these landmarks, a 22-gauge spinal needle was introduced slowly to a depth of approximately 8 cm. At this point, the patient winced and then withdrew her right leg. Following demonstration of inability to aspirate fluid, 30 ml of a 1% lidocaine solution with 1:200,000 epinephrine was injected and the needle withdrawn. The sensory level of anesthesia was difficult to establish because of the patient's abnormal mental status.

Within 10 minutes of injection, the patient was unresponsive to verbal and sensory stimulation and then became apneic. She was immediately ventilated with 100% O_2 per face mask and oral airway; blood pressure was 95/55 torr and pulse rate 60 bpm. The operative procedure was now begun. The ECG, showing sinus rhythm with occasional atrial premature contractions, was unchanged, and the pupils were in midposition and not dilated. Thirty minutes after lidocaine injection, blood pressure had decreased to 80/40 torr, returning promptly to 100/50 torr following 25 mg of IV ephedrine sulfate. Pulse rate showed only modest changes during both the initial fall in pressure and the response to ephedrine.

Fifty-five minutes after injection, as the surgical procedure was being completed, the patient began to demonstrate weak but definite spontaneous respiratory efforts, and her pupils were central but widely dilated. The trachea was easily intubated without the use of muscle relaxants and she was transported to the recovery room. Ventilation was controlled until there was demonstration of a clinically adequate tidal volume, with apparent full return of muscle strength and marked improvement in alertness. The patient was then extubated and returned to her room. The remainder of the postoperative course was uneventful, and the patient was discharged on the 23rd hospital day.

DISCUSSION

Rapid, unexpected obtundation and respiratory paralysis were serious complications of this regional anesthetic procedure. The absence of focal or localizing neurologic signs either intraoperatively or in the immediate postoperative period would make the possibility of an acute cerebrovascular accident remote. There had been no history or evidence of recurrent transient cerebral ischemic episodes. It was presumed, therefore, that the complications were directly related to the anesthetic itself.

The lumbosacral plexus block was performed using the technic of Winnie's group.[1] However, we reduced the recommended volume of anesthetic agent, 40 ml, to 30 ml, in view of the patient's debilitated condition. Although we could not elicit a classic paresthesia to document needle position, we did obtain a response from the patient which was thought to be a confirmation of correct position of the needle.

Direct IV injection or rapid absorption of lidocaine from the injection site can produce high plasma levels of the drug. Signs of systemic toxicity may include loss of consciousness without associated seizures or cardiovascular collapse,[2] but the gradual onset and slow resolution of the alteration in consciousness suggest an alternative explanation.

The time interval prior to the onset of diaphragmatic paralysis and the fairly rapid return of function suggest epidural spread of the injected anesthetic. An inadvertent subarachnoid injection would be expected to have produced apnea both earlier in onset and of longer duration than was observed. In addition, one would have expected rapid development of profound hypotension following an extensive spinal anesthetic. Within 10 minutes of administration of deliberate spinal anesthesia several days earlier, the patient's mean arterial blood pressure (MAP) fell to 44% of initial value. Multiple IV infusions of ephedrine sulfate were required over the subsequent 2-hour period to maintain blood pressure at acceptable levels. In contrast, the attempt at lumbosacral plexus block produced a slowly progressive, mild hypotension: the minimum MAP, observed 30 minutes after anesthetic injection, was 70% of starting value.

Epidural spread following plexus block anesthesia has been described previously,[3] but with regard to the brachial plexus. Shantha and Evans[4] have explained spinal and epidural-type blocks after peripheral nerve blocks by subpial, subperineural, and interperineural epithelial spread from the

periphery. In addition, Evans and coworkers[5] have described spread of local anesthetic following a paravertebral sympathetic block procedure, producing epidural anesthesia; they claim that this demonstrates extraneural communications between the paravertebral and epidural spaces.

We believe that the generalized arteriosclerotic disease of this patient contributed to the intensity and level of blockade. Bromage[6] has found that segmental analgesia in patients with occlusive vascular disease may spread 1½ to 3 times further than in normal subjects. Certainly, when an epidural anesthetic is performed, reduced dosage of the agent is indicated in the elderly arteriosclerotic individual.

The anesthetic injection in this patient was probably not directly into the epidural space, as the needle was 5 cm from the midline, but we cannot exclude this possibility; with seepage of even a fraction of the total dose of anesthetic, an exaggerated block effect would be expected.

Prolonged Neuromuscular Blockade Associated with Trimethaphan: A Case Report

SUSAN L. WILSON, MD*
ROBERT N. MILLER, MD†
CARMEN WRIGHT, CRNA‡
DIANE HASSE, CRNA§

A case of prolonged neuromuscular blockade associated with the administration of trimethaphan to a neurosurgical patient aged 29 is believed to be the possible result of interaction between trimethaphan, a ganglionic-blocking drug, and muscle relaxant. This possibility should be kept in mind when the administration of trimethaphan is being considered.

THE concept of interaction between ganglionic-blocking agents and neuromuscular transmission is not new, although infrequently encountered. The following case report serves as an example of such interaction.

REPORT OF A CASE

A 29-year-old previously healthy man was admitted to the hospital following the sudden onset of a bifrontal headache with brief lapses into unresponsiveness. Physical examination revealed a lethargic, irritable man weighing 66 kg, with slight nuchal rigidity and no lateralizing signs. The results of a lumbar puncture showed an opening pressure of 500 mm H_2O, with bloody cerebrospinal fluid (CSF). Angiography showed an aneurysm at the apex of the basilar artery and another at the left middle cerebral trifurcation. Chest x-ray, ECG tracing, and SMA-12 were within normal limits.

Eleven days after admission, the patient was brought to the operating room for ligation of his basilar aneurysm through a right temporal craniotomy. He was premedicated with pentobarbital (100 mg) and atropine (0.4 mg) IM, 1 hour before induction of anesthesia. Sleep was induced at 0730 hours with IV sodium thiopental (250 mg) and meperidine (30 mg). After pretreatment with d-tubocurarine (6 mg) IV, the patient was given succinylcholine (100 mg) to facilitate intubation of the trachea, and a 9-mm cuffed endotracheal catheter was placed in the trachea without difficulty. The monitors chosen for this patient included a continuous ECG, a precordial stethoscope, and an esophageal temperature probe. A Doppler monitor was used for auscultation of blood pressure in the upper extremity, insertion of a Foley catheter allowed continuous observation of urine output, and a spinal needle was placed in the subarachnoid space to

indicate the clarity and flow characteristics of the CSF.

Between 0730 and 1000 hours, the patient was given incremental doses to a total of 54 mg d-tubocurarine (dTc), 50 mg meperidine, and 450 mg sodium thiopental IV. He was ventilated with N_2O-O_2 (67:33%) at a rate of 14 times/min, with a 750 ml tidal volume. Blood pressure had been reduced through the combined use of trimethaphan and halothane to 60/40 torr at 1025 hours. The lowest systolic blood pressure reached was 30 torr. The duration of the hypotensive period was 75 minutes. The trimethaphan and halothane were discontinued at 1135, following entrapment of the aneurysm, and the blood pressure returned to 110/40 torr after 3 phenylephrine IV washes. Total dose of trimethaphan was 4500 mg during the 90-minute period of administration.

The patient had been allowed to cool to an esophageal temperature of 35 C, noted at 1130, but the temperature had risen to 36° by 1230. Urine output during the procedure was greater than 100 ml/hr, 100 ml being eliminated the 1st hour after discontinuing the trimethaphan. A total of 5000 ml of fluid, including 2000 ml D/5 normal saline solution, with trimethaphan 2000 ml D/5 lactated Ringer's solution, and 1000 ml lactated Ringer's solution were administered during the procedure; no blood was administered. At the conclusion of the operation at 1315 hours, the patient was given atropine (1.8 mg) and neostigmine (4 mg) and N-allyl oxymorphone (0.2 mg) IV. During the next 25 minutes, the patient remained apneic and was hypoventilated to allow an increase in $Paco_2$ to stimulate ventilation.

However, he showed no demonstrable reversal of neuromuscular blockade. There was no response to ulnar nerve stimulation by Block-Aid® monitor. Arterial blood withdrawn at 1340 hours revealed a significantly elevated $Paco_2$ and commensurately lowered pH, consistent with deliberate hypoventilation. More vigorous ventilation was instituted and additional atropine (0.6 mg) and neostigmine (1.5 mg) was given IV. By 1430, the patient was beginning to initiate gross movements of all extremities and was responsive to commands.

He was taken to the recovery room at 1500 hours, where ventilation was assisted with a Bennett respirator at an FIO_2 of 1. Arterial blood withdrawn in the recovery room revealed pH 7.45, $Paco_2$ 27, Pao_2 454. Within another 45 minutes, the patient was able to ventilate spontaneously and had a vital capacity of 1500 ml. At this time, he was extubated. The arterial blood was again sampled, after 10 minutes of O_2 administered by mask, and gave a $Paco_2$ of 33 and Pao_2 of 132, with a pH of 7.38. Serum Na^+, K^+, and Cl^- were within normal limits. The remainder of the postoperative course was uneventful.

Approximately 3 weeks later the patient was again brought to the operating room for resection of the aneurysm involving his middle cerebral artery. The anesthetic technics and agents used were essentially the same as for his previous operation, with the following exceptions:

(1) Total dose of dTc given in increments over the first 2 hours was 69 mg.

(2) Halothane was administered initially, beginning 2 hours after induction, for 110 minutes, with blood pressure maintained at 120/80 torr, at which time the trimethaphan drip was begun with immediate response to 60/40 torr. Total dose of trimethaphan was 35 mg over a 10-minute period. Upon discontinuation of the halothane and trimethaphan, the blood pressure rose to 120/80 torr without administration of a vasopressor. The neuromuscular junction was monitored frequently and post-tetanic facilitation was noted throughout the procedure. At the end of the operative procedure, which lasted 5 hours and 50 minutes, the patient was initiating ventilation before the IV administration of atropine (2 mg) and neostigmine (5 mg). The patient was extubated without difficulty and made an uneventful recovery. He was discharged from the hospital 10 days after the second craniotomy.

DISCUSSION

The problem presented in the care of this patient involves the differential diagnosis of persistent postoperative neuromuscular blockade. Hypocarbia as a cause of postoperative apnea was ruled out early when the patient did not respond to hypoventilation carried to excess. Hypercarbia with acidosis is another cause of postoperative apnea; however, there is no reason to suspect that acidosis existed prior to deliberate hypoventilation. The induced acidosis may have, however, added to the already existing problem. One would expect to find marked cerebral vasodilation and increased cerebral blood flow secondary to an acute

increase in $Paco_2$, as seen when the patient was deliberately hypoventilated.

Hypothermia was not a problem. The patient did not receive any of the drugs commonly recognized to potentiate neuromuscular blockade, such as antibiotics, procaine, quinidine, guanethidine, or cholinesterase inhibitors. Central depression secondary to barbiturate, narcotic, or halothane remains a possibility, as does edema of the brainstem. The total dose of thiopental was not excessive. The concentration of halothane was 1.5% and its total duration of administration was 1 hour. Moreover, the patient had not received halothane for 90 minutes prior to the attempted reversal of neuromuscular blockade. N-allyl-oxymorphone was given but the patient did not respond to the small dose (0.2 mg) given. An abnormality of pseudocholinesterase is unlikely on the basis of the patient's response to his second anesthetic.

There was no history of exposure to cholinesterase inhibitors, but this possibility remains. The initial dose of neostigmine was somewhat less than the 0.07 mg/kg recommended by Churchill-Davidson, but one should still expect some degree of reversal with this dose, particularly since the last dose of dTc had been given some 210 minutes before administration of the reversal drug.

Another possibility is a neurologic (brainstem) catastrophe, which can be ruled out on the basis that this patient finally responded and was neurologically intact. Transient brainstem swelling cannot be ruled out. Serum Na^+ and K^+ before and immediately after operation were within normal limits. Serum Mg^{++} and ionized Ca^{++} were not measured.

Reduced blood flow to tissues, especially muscle and kidney, during induced hypotension could be expected to affect the kinetics of muscle relaxant distribution. With a fall in muscle perfusion, one would expect a delay in removal of displaced nondepolarizing relaxant drug from the neuromuscular junction, thereby prolonging the neuromuscular block. In this patient, blood pressure was restored by several IV phenylephrine washes. Renal blood flow appeared adequate at all times because of the acceptable urinary output, but one cannot be sure of the total perfusion to the muscle mass. Thus, the effect of hypotension on redistribution of dTc could help to explain the observed prolonged neuromuscular blockade. However, there was a period of 90 minutes between the restoration of blood pressure and the attempted reversal of the neuromuscular blockade, making a redistribution phenomenon an unlikely explanation.

Finally, a not-so-commonly considered factor, and perhaps the etiologic mechanism in this patient, is the interaction between trimethaphan, a ganglionic-blocking drug, and the muscle relaxant used.

As early as 1949, Randall and associates[1] noted the existence of muscle weakness in dogs treated with trimethaphan. The explanation proposed was associated hypotension rather than a true interaction of the drug with the neuromuscular junction. Later work by Pearcy and Wittenstein[2] showed prolonged apnea in rats with administration of trimethaphan, but without severe depression of blood pressure. In 1957, Tewfik[3] noted prolongation of succinylcholine-induced apnea in patients treated with trimethaphan. He demonstrated *in vitro* that trimethaphan was a potent inhibitor of pseudocholinesterase and postulated that the drug was metabolized by pseudocholinesterase, inducing temporary inhibition.

Pearcy and Wittenstein[2] attempted to test Tewfik's[3] postulate. Their interpretation was that trimethaphan was not destroyed by pseudocholinesterase to any substantial extent. In addition, in rats given large doses of trimethaphan (25 mg/kg), they observed brief periods of apnea resembling the apnea following muscle relaxation.

Deacock and Davies,[4] using a rat-diaphragm model, observed in their preparation that "trimethaphan produced neuromuscular block after 60 mg had been given, but only 20 mg was required after partial curarization," and that "neostigmine increased the degree of neuromuscular block in preparations recovering from trimethaphan."

If trimethaphan (*in vivo* as well as *in vitro*) is a cholinesterase inhibitor, then in large doses as administered to the patient under consideration, one might observe an acetylcholine-induced block. One would expect neostigmine to augment such a neuromuscular inhibition. If trimethaphan is metabolized by serum pseudocholinesterase in man, perhaps one could observe substrate inhibition with very large doses. This problem could be augmented by the administration of neostigmine. Either of the above explanations is possible with respect to the persistent postoperative neuromuscular

blockade observed in this patient. Another possibility is a complex interaction at the neuromuscular junction between ganglion-blocking agents (like trimethaphan) and nondepolarizing muscle relaxants (such as dTc or pancuronium). Such an interaction has been demonstrated in the laboratory by Deacock and Davies.[4]

There appears to be a complex but well established interaction between the ganglionic-blocking agents, trimethaphan, and neuromuscular blockade, at least when very large doses of trimethaphan are used. It would seem advisable to keep this interaction and its possible consequences in mind when considering agents and technics of hypotensive anesthesia, and consider abandoning trimethaphan and switching to another hypotensive technic in patients who, seemingly refractory to the agent, require larger and larger doses to obtain the desired hypotensive effect.

MEDICAL STATISTICS

Statistical Pearls. II How Often Did That Happen?

PATRICK D. HARRIS, PhD*

TOM MUSACCHIA, the young internist and budding researcher, hurried to catch David Wiegman, who was considered to be the best at the numbers game. "David!" "Hi, Tom." Dr. Musacchia proceeded to relate his problem. "I have serum total cholesterol on 110 male patients that I want to use as a control group for a lipid metabolism study. The *mean* is a little high, but I'll never be able to show any significant differences with the range that I have in this control group." David thought for a moment, and then, "Does your distribution look good?"

"Distribution?" Tom asked. "I just assumed a *normal curve*."

"Well, Tom, you have enough observations to get at least a feel for the homogeneity of your control group. You might have a large range because your control data are derived from more than one statistical population."

Since Dr. Musacchia was not familiar with technics of looking at distributions, Dr. Wiegman described a simple, but reasonably accurate approach to the construction of a *histogram*.[1] Cholesterol had been measured to the nearest 1 mg/100 ml to give a mean value of 267 mg/100 ml, with a range of 145 to 437 mg/100 ml. Since 8 to 15 *class intervals* of equal size are desirable for a histogram, an initial value of 140 mg/100 ml and a class interval of 20 mg/100 ml (437 − 145 = 292 mg/100 ml range; 292/15 ≒ 20 mg/100 ml for the interval size) were arbitrarily chosen. This gave class intervals of 140-159, 160-179, 180-199, 200-219, 220-239, 240-259, 260-279, 280-299, 300-319, 320-339, 340-359, 360-379, 380-399, 400-419, and 420-439. The starting point of 140 mg/100 ml was selected so that the mean value for the data (267 mg/100 ml) fell close to the midpoint (269.5) of one of the class intervals (260-279).

*Investigator, Dalton Research Center; Associate Professor of Physiology, University of Missouri School of Medicine, Columbia, Missouri 65201.

Following this choice of intervals, a *frequency table* was obtained by counting the number of cholesterol measurements that fell within each interval. Dr. Wiegman illustrated this procedure by noting that, of the total of 110 measurements, there was only one value (145 mg/100 ml) which fell in the 140-159 interval. Thus, the frequency was 1 for the 140-159 class interval. The measurements 160 and 171 mg/100 ml were the only values in the 160-179 class interval, so the frequency was 2 for that interval.

Dr. Wiegman explained that a histogram is merely a vertical bar graph in which the width of each bar is the class interval and the height of each bar is the frequency for that interval. He also emphasized that it is easier to compare 2 histograms if the frequency for each class interval in a histogram is expressed as a percentage of the total number of measurements in that histogram.

Dr. Musacchia obtained the frequency table, drew the bar graph, returned to Dr. Wiegman's office, and presented his chart (fig 1), remarking: "Well, I guess I have a normal distribution." After a minute of study, Dr. Wiegman commented: "This distribution is fairly symmetrical, but I wonder about the shape. Most of the time, a homogeneous group of data will have a mean that falls in, or next to, the class interval that has the highest frequency. In this distribution, the highest frequency occurs for the class interval 220-239 while the mean (267) is located 2 class intervals away (in 260-279). In addition, I would expect the frequency to decrease for the class intervals on either side of the mean. But, Tom, your data have 5 class intervals which have about the same frequency. This suggests a nonhomogeneous group of data. I would recommend that you go back to the raw measurements and try to divide them into at least 2 groups on the basis of some characteristic in the histories of these patients."

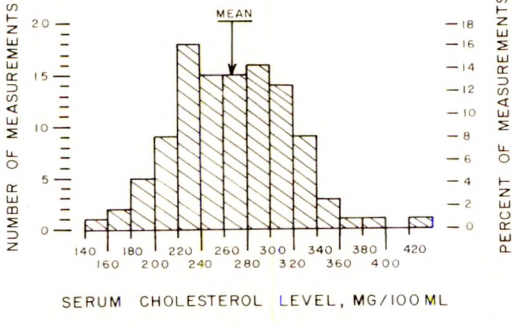

FIG 1. Histogram for 110 measurements of serum total cholesterol. The numbers on the abscissa identify the lowest cholesterol value in each class interval. The left ordinate scale gives the height of each bar as the *number* of measurements which fell within each class interval. The right ordinate scale gives the height of each bar as the *percentage* of total measurements which fell in each class interval.

Dr. Musacchia knew that a number of the patients in his control group had a history of myocardial infarction, but these patients were stable, with no significant weight changes and no special diets. Yet, it has been proposed that atherosclerosis in man is related to a disorder of lipid metabolism.[2,3] So he classified his patients into those who had the *attribute of a prior myocardial infarction*[3] and those with the *attribute of no history of myocardial infarction*.[2] He then obtained a frequency table and constructed a histogram for each of these 2 groups.

"David, this is amazing! I want you to look at these distributions (fig 2) for pa-

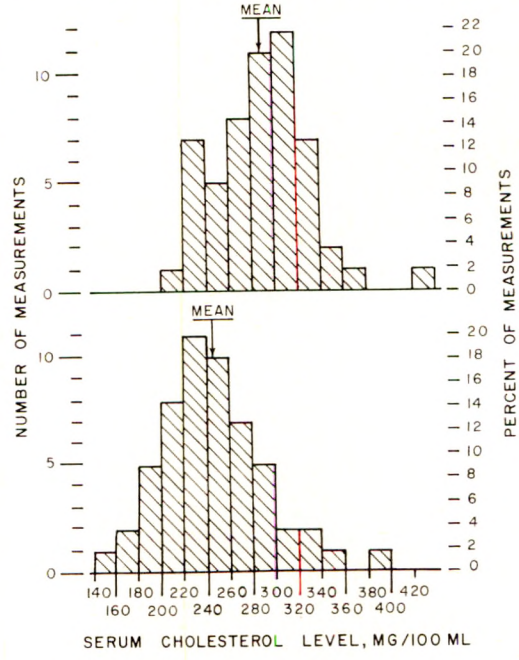

FIG 2. Bottom panel: Histogram for measurements of serum total cholesterol from 55 patients who had no prior history of myocardial infarction. These data were derived from the statistical characteristics of the Harvard group in reference 2 and are contained in the histogram in figure 1. Top panel: Histogram for measurements of serum total cholesterol from 55 patients (ages 40-59) who had a previous history of myocardial infarction. These data were derived by adding 20 mg/100 ml to each of the values in the Appendix Table A in reference 3. These data are also contained in the histogram in figure 1.

tients with and without a prior history of myocardial infarction!" Dr. Wiegman studied the graphs for only a brief moment. "I do believe you have something, Tom. In the noninfarcted group (fig 2, bottom panel), the mean is 245 and is very close to the interval (220-239) with the peak frequency. In the infarcted group (fig 2, top panel), the mean is 290 and is also close to the interval (300-319) with the peak frequency. In both histograms, there is a reasonably good decrease in frequency for class intervals on each side of the peak frequency. The class interval 220-239 for the group of infarcted patients is somewhat unusual, but you would need more measurements before you could further subdivide this group of infarcted patients. In general, one needs at least 8 class intervals and 40 observations to make a reasonable attempt to *describe data by a histogram*."

"Thanks, David. It is now apparent that I should limit the control and experimental groups in my lipid metabolism study to patients without a history of myocardial infarction. On the other hand, I could also have control and experimental groups of patients who have previously infarcted. Their lipid metabolism might be considerably different in comparison to noninfarcted patients."

"Just think, Tom, this point was almost missed because you calculated a *mean* and range as the *first* step in looking at your data." Tom thought for a moment. "David, I sure didn't *mean* to do that."

The Effect of Enflurane, Isoflurane, Fluroxene, Methoxyflurane and Diethyl Ether Anesthesia on Ouabain Tolerance in the Dog

ANTHONY D. IVANKOVICH, MD*

VINCENT J. CAIROLI, PhD**

Digitalis tolerance in dogs anesthetized with enflurane, isoflurane, fluroxene, methoxyflurane, and diethyl ether was compared with that in dogs anesthetized with pentobarbital. Ouabain dosage needed to cause ventricular tachycardia was significantly higher than that of pentobarbital with all agents except fluroxene, as was the LD_{50}. The relative potency of these anesthetics in converting ouabain-induced ventricular tachycardia to sinus rhythm, in order of descending effectiveness, was: diethyl ether, methoxyflurane, enflurane, fluroxene, isoflurane, pentobarbital.

THE effect of anesthetic agents on digitalis tolerance is of considerable practical as well as theoretic interest, especially with a burgeoning geriatric population calculated to increase the incidence of digitalized surgical patients. Since the therapeutic index for digitalis glycosides is quite small, knowledge concerning digitalis-anesthetic interactions is imperative in selecting safe, effective drug combinations.[1,2]

Previous investigators have demonstrated digitalis toxicity to be reduced by epidural[3] or systemic lidocaine,[4] halothane,[5] and methoxyflurane,[6] increased by cyclopropane,[5] and unchanged by barbiturates.[5,7] In 1971 and subsequently, we reported that ketamine and neuroleptanesthesia increased tolerance to digitalis-induced arrhythmias.[8,9] This report extends information on the digitalis-anesthetic interaction for some standard and experimental anesthetic agents.

METHODS

Two series of experiments were performed on 120 unpremedicated dogs, each weighing between 15 to 20 kg. In the first series, 60 dogs were divided into 6 equal groups, according to the anesthetic employed: (1)

pentobarbital (control), (2) fluroxene, (3) isoflurane, (4) methoxyflurane, (5) enflurane, and (6) diethyl ether, and digitalis tolerance was determined by ascertaining the ouabain dosage required to produce ventricular tachycardia (VT) and death.

After achieving satisfactory anesthesia using a face mask for the inhalational anesthetics, or an induction dose of 35 mg/kg IV for pentobarbital, the animals were intubated endotracheally with a cuffed tube and respiration was controlled by a Harvard respiratory pump using 100% O_2. The femoral artery was cannulated to monitor arterial blood pressure, and a femoral vein was cannulated for ouabain infusions. In pentobarbital-anesthetized dogs, both femoral veins were cannulated, one for continuous administration of ouabain and the other for intermittent administration of pentobarbital. An ECG (lead II) and arterial blood pressure were continuously displayed, and tracings were recorded as appropriate. Heart rate was determined from the ECG record. Arterial blood gases were measured periodically, and arterial concentrations of the anesthetic agents were analyzed by flame ionization detector.[10] Ventilation was adjusted to maintain $Paco_2$ at approximately 35 torr, and any base deficit in excess of 5 mEq/L was corrected with $NaHCO_3$. Temperature was maintained between 37 and 39 C.

Ouabain was administered by constant-infusion pump at a rate of 35 mcg/kg/hr. The cumulative dose of ouabain required to produce VT (3 or more consecutive premature ventricular contractions) and death was determined for each animal and then averaged for each group. Results were analyzed for statistical significance by fixed analysis of variance within each group.

In the second series, 60 animals were anesthetized with pentobarbital, intubated, ventilated with 100% O_2, and managed exactly as were the dogs in the pentobarbital group in the first part of the study. Ventricular tachycardia was induced by continuous infusion of ouabain (35 mcg/kg/hr). About 3 minutes after the onset of VT, either 150 mg of pentobarbital was given IV or 5 to 7% of enflurane or isoflurane, 8 to 10% fluroxene, 2 to 3% methoxyflurane, or 15 to 25% of diethyl ether was introduced into the anesthetic system. The ouabain infusion was continued during these maneuvers. Immediately following conversion of VT to sinus rhythm, arterial blood was withdrawn for the estimation of blood gases and anesthetic blood levels.

RESULTS

1. *Ventricular Tachycardia* (fig 1).—The mean dose of ouabain (in mcg/kg) required to produce VT in dogs anesthetized with pentobarbital was 53.4; with fluroxene, 60.1; with isoflurane, 69.4; with methoxyflurane, 81.3; with diethyl ether, 90.4; and with enflurane, 92.8. The ouabain dosage for the last 4 anesthetics was significantly higher than that for pentobarbital ($p<0.01$ to 0.005). The difference in dosage between fluroxene and pentobarbital was not statistically significant.

2. *Mean Lethal Dose* (MLD) (fig 2).—The MLD of ouabain (in mcg/kg) in dogs

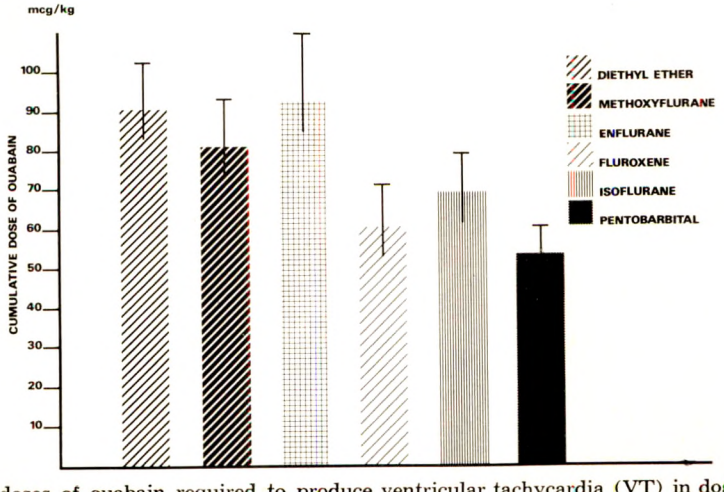

FIG 1. Average doses of ouabain required to produce ventricular tachycardia (VT) in dogs anesthetized with agents studied. Each value represents mean and SD of 10 experiments.

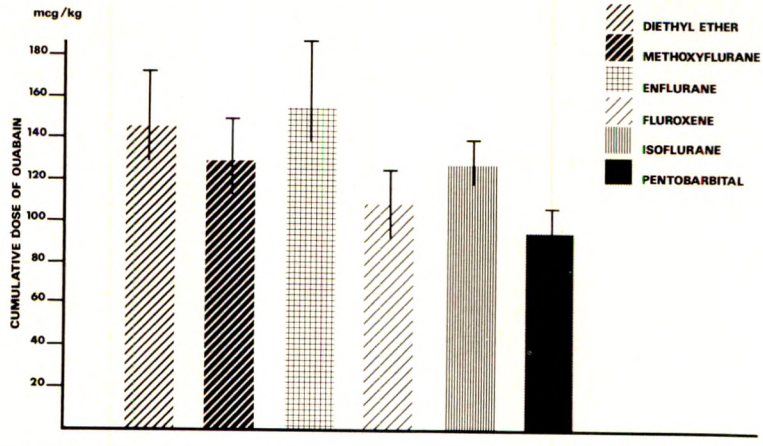

FIG 2. Average lethal doses of ouabain in dogs anesthetized with agents studied. Each value represents mean and SD of 10 experiments.

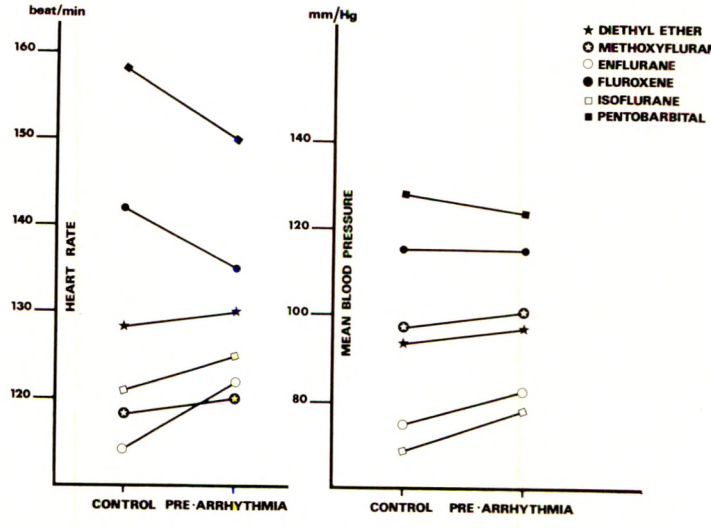

FIG 3. Average heart rates and MAP during ouabain infusion. Control values were calculated just before ouabain administration and prearrhythmia values were determined immediately before appearance of VT. Each value represents mean of 10 experiments.

anesthetized with pentobarbital was 95.2; with fluroxene, 108; with isoflurane, 127.5; with methoxyflurane, 128.9; with diethyl ether, 145.1; and with enflurane, 156.4. The dosage for isoflurane, methoxyflurane, diethyl ether, and enflurane was significantly higher than for pentobarbital.

The difference in dosage between fluroxene and pentobarbital again was not statistically significant. Death in pentobarbital-anesthetized animals was almost always due to ventricular fibrillation, while dogs anesthetized with the other agents invariably died in cardiac asystole.

3. *Mean Heart Rate and Blood Pressure Values* (fig 3).—Control values for heart rate and blood pressure were taken before the ouabain infusion was started, and prearrhythmia values were determined just before the appearance of premature ventricular contractions. Both control and prearrhythmia mean blood pressures and heart rates were lower for isoflurane, methoxyflurane, enflurane, and diethyl ether than for pentobarbital or fluroxene. These parameters did not change significantly during digitalization in any of the groups.

4. *Effects of Anesthetic Agents on Ouabain-Induced VT* (fig 4).—Since previous studies[3,9] indicated that 5 minutes or less after the onset of VT was an optimal time to administer agents for conversion of VT

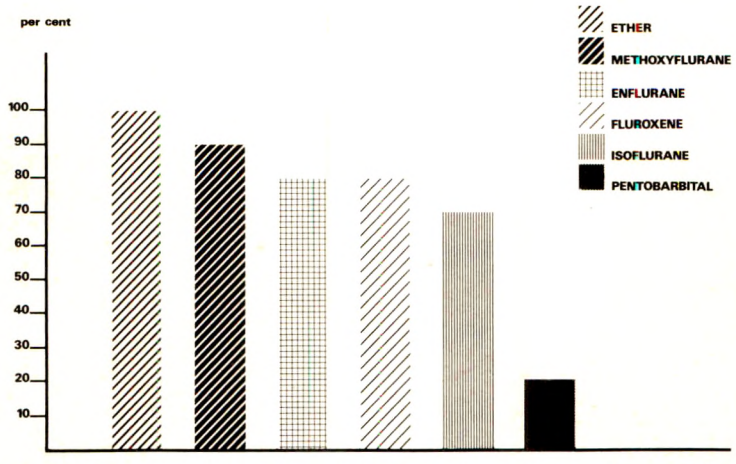

FIG 4. Percentage of dogs converted to sinus rhythm by each anesthetic, subsequent to an initial 3-minute oaubain-induced VT. Each value is based on 10 dogs per anesthetic agent.

to sinus rhythm, the 6 agents under study were administered 3 minutes after the onset of VT, and the ouabain infusion was continued. The intervention of the anesthetics resulted in the following conversions of VT to sinus rhythm: diethyl ether, 10/10 dogs; methoxyflurane, 9/10; enflurane and fluroxene, 8/10; isoflurane, 7/10; and pentobarbital, 2/10. The average time from the administration of the anesthetic until conversion was approximately 1 minute for diethyl ether, and between 3 and 4 minutes for the other general anesthetics. The mean arterial blood concentration following conversion of VT to sinus rhythm (in mg %) was 25.5 for diethyl ether; 8.3 for methoxyflurane; 7.9 for enflurane; 12.3 for fluroxene; and 6.9 for isoflurane. These experiments were terminated shortly after conversion of VT to sinus rhythm was established.

Mean blood pressures before and after conversion of VT to sinus rhythm are shown in figure 5. On a percentage basis, the smallest decrease in blood pressure (9%) was seen following conversion with pentobarbital and with diethyl ether. Pentobarbital was least effective and diethyl ether most

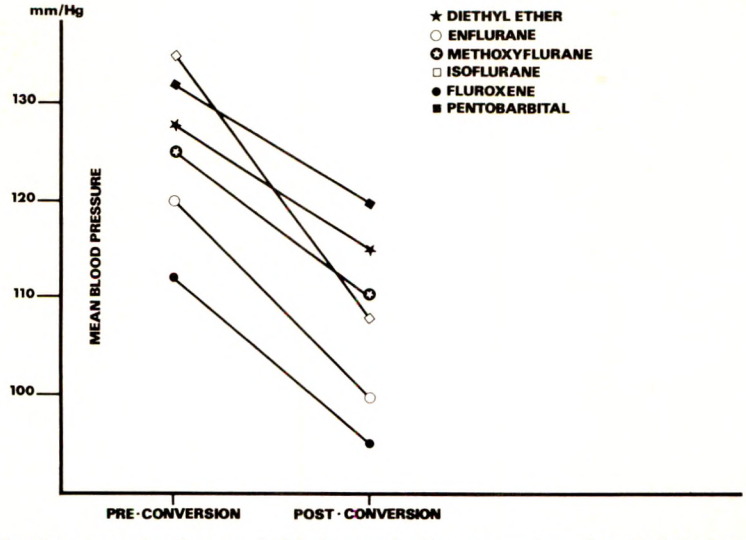

FIG 5. Mean blood pressure levels recorded before and after conversion of oaubain-induced VT to sinus rhythm. Preconversion values were recorded during pentobarbital anesthesia and represent the average during 3 minutes of ouabain-induced VT. Postconversion values were recorded immediately after conversion to sinus rhythm. Each value represents the mean for only those dogs successfully converted.

effective in converting VT to sinus rhythm, suggesting that decreased blood pressure was not the sole factor in VT conversion.

DISCUSSION

At full digitalization, a patient will have received more than 60% of the toxic dose, while at the onset of toxicity, he will have received as much as 50% of the lethal dose. Given this narrow margin of safety between the full therapeutic, toxic, and lethal doses, any modification of digitalis action, particularly by drug interactions, can easily result in under- or overdigitalization. As previously reported,[11] a number of diverse factors possess this capability: drugs, electrolyte disturbances, autonomic nerve function, hypoxia, changes in blood pH, and body temperature, among others.

Morrow was one of the first to demonstrate that anesthetic agents significantly modify the effects of digitalis glycosides (ouabain, digoxin). He reported that tolerance to digitalis toxicity was increased by halothane, decreased by cyclopropane, and unchanged by pentobarbital, with no effect on the therapeutic positive-inotropic response.[5-7] The clinical importance of this subtle phenomenon for the anesthesiologist pertains to both digitalized and undigitalized patients. If an anesthetic increases tolerance to digitalis, a fully digitalized patient becoming underdigitalized during anesthesia may develop heart failure, while in a fully digitalized patient anesthetized with agents which decrease tolerance to digitalis, arrhythmias and other signs of digitalis toxicity might appear during the anesthetic period. Also, if a previously undigitalized patient develops heart failure during anesthesia, more digitalis might be needed to achieve a therapeutic effect, were the patient anesthetized with an agent that increases tolerance to digitalis. Following emergence from anesthesia, when the protective effect of the anesthetic is lost, this patient might develop digitalis intoxication.

The present study shows that diethyl ether, methoxyflurane, enflurane, and isoflurane increased tolerance to digitalis toxicity when administered before ouabain infusion and restored sinus rhythm when administered acutely during ouabain-induced VT. However, while pretreatment with fluroxene did not affect myocardial sensitivity to ouabain toxicity, when fluroxene was administered acutely during ouabain-induced VT, it successfully converted 8/10 dogs to sinus rhythm. These results emphasize that in cases of digitalis toxicity, a drug useful for therapy may not necessarily be the drug of choice for prophylaxis.

Halothane and methoxyflurane have been reported to produce a dose-dependent increase in the atrioventricular functional refractory period, independent of autonomic nervous-system activity.[6] In addition, there is evidence that halothane decreases intrinsic ventricular automaticity:halothane depressed ventricular escape pacemaker activity during vagal stimulation before and after ouabain-induced VT,[12] and suppressed spontaneous phase-4 depolarization in Purkinje fibers *in vitro*.[13] Thus, halothane and methoxyflurane possess characteristic intrinsic, antiarrhythmic properties which could explain the increased tolerance to ouabain toxicity, as well as the reversal of ouabain-induced VT, observed in this study.

The sympathetic nervous system is stimulated by digitalis at all levels, from central to peripheral sites, and is believed to be involved in the genesis of digitalis-induced ventricular arrhythmias.[14] Thus, anesthetics such as cyclopropane, which enhance sympathetic activity, also increase digitalis toxicity. Conversely, there is evidence that halothane[15] and isoflurane[16] decrease sympathetic nervous activity which may contribute to the increased tolerance to digitalis toxicity conferred by these agents.

It has been reported[17] that an increase in blood pressure decreases the threshold for the genesis of arrhythmias, perhaps due to the related augmentation of sympathetic nervous activity, or an increased cardiac afterload. Consequently, the decrease in blood pressure produced by the more effective inhalational anesthetics in this study may be an ancillary factor in further protecting against digitalis toxicity.

Heart rate is known to influence both the therapeutic and toxic actions of digitalis, presumably mediated via ion-exchange mechanisms involving calcium and potassium.[18] An increase in heart rate has been shown to increase K^+ efflux, with a concomitant decrease in myocardial K^+, considered a major mechanism of digitalis toxicity.[19] Thus, there is an inverse relationship between heart rate and the toxic or lethal dose of ouabain.[20] However, as this phenomenon appears to be more important at higher heart rates,[18] the decrease in such rates produced by anesthetic agents is probably a minor factor in their protective action against digitalis toxicity.

Another possibility for an antiarrhythmic property has been revealed by recent studies with ^{42}K exploration of the effects of anesthetics on K^+ movements.* Preliminary data indicate that halothane and methoxyflurane decrease K^+ efflux, preventing the intracellular loss of this ion. Thus, these inhalational anesthetics may stabilize excitable membranes and exert an antiarrhythmic action similar to that of local anesthetics.

Editors share the belief that medical writing is capable of vast improvement. This article is one of a series of personal communications from Charles G. Roland, M.D., former Senior Editor of JAMA, to John T. Martin, M.D., Associate Editor of Anesthesia & Analgesia . . . Current Researches. Dr. Roland is Chairman, Department of Biomedical Communications, Mayo Clinic, Rochester, Minnesota 55901.

Thoughts About Medical Writing

XXXV. "Let's Call It Hebetization"

Dear Tom:

All inventions seem to have at least one thing in common. Each needs a name. Without a name, it can't be talked about.

When Morton finally convinced the medical Brahmins of Boston that "Letheon" worked—by convincing a distinguished group of surgeons at the Massachusetts General Hospital—they were all promptly put in need of a proper descriptive name. Morton's own "Letheon" raised problems at once—it was a trade name and he sought a patent, a most unmannerly thing to do. Besides, several of the surgeons knew perfectly well that the active agent, or one of the active agents, was ether. Its odor is distinctive and was well known even then.

Many names were suggested during the first few months after October 16, 1846. One of these was hebetization.[1] I don't know who contributed this name. But think on it. You might have become a hebetiziologist and an editor for the journal *Hebetization and Analgesia . . . Current Researches.* Even so, I don't suppose it would have changed your life. The name is *not* the thing.

Nevertheless, we don't talk about hebetizing a patient. How did "anesthesia" and its various congeners come to be accepted? Holmes, you say?

Probably every anesthesiologist and anesthetist knows the name of Oliver Wendell Holmes. It was, after all, that great Bostonian who has received credit for recommending the use of the word "anaesthesia" to describe the state of insensibility following the inhalation of ether. But is the credit deserved?

Authorities differ. That epitome of historical linguistic authority, the *Oxford English Dictionary,* does not mention Holmes. "Anaesthesia" (following the British spelling) has been traced to 1721, when Bailey used the word to describe a defect of sensation, as in "Paralytic and blasted Persons."[2] The OED then gives an 1848 authority for a totally modern use of the word—and cites Sir J. Y. Simpson, writing in the *Pharmacological Journal*: "The state of anaesthesia lasted for two or three minutes." "Anaesthetic," in all but one of its several meanings, is also credited to the dour Scot, as is "anaesthetize."

Where is Oliver Wendell Holmes in all this? How did Simpson steal all the glory? Is there a chauvinistic plot by the compilers

of the OED to keep the credit, if not in England, at least in the British Isles?

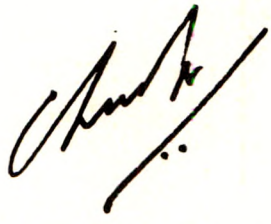
Not really. The OED is based on published—and therefore traceable and verifiable—sources. Holmes' contribution seems to have been made in the form of a letter to W. T. G. Morton, written on November 21, 1846,[3] but apparently not published till 1859.[4] Holmes wrote:

> My Dear Sir,—Everybody wants to have a hand in a great discovery. All I will do is to give you a hint or two, as to names, or the name, to be applied to the state produced and the agent.
>
> The state should, I think, be called "Anaesthesia." This signifies insensibility, more particularly (as used by Linnaeus and Cullen) to objects of touch. (See Good—*Nosology*, p. 259). The adjective will be "Anaesthetic." Thus we might say, the state of anaesthesia, or the anaesthetic state. The means employed would be properly called the anti-aesthetic agent. Perhaps it might be allowable to say anaesthetic agent, but this admits of question.
>
> The words, antineuric, aneuric, neuro-leptic, neurolepsia, neuro-etasis, etc., seem too anatomical; whereas the change is a physiological one. I throw them out for consideration.
>
> I would have a name pretty soon, and consult some accomplished scholar, such as President Everett or Dr. Bigelow, senior, before fixing upon the terms, which will be repeated by the tongues of every civilized race of mankind. You could mention these words which I suggest for their consideration; but there may be others more appropriate and agreeable.
>
> Yours, respectfully,
>
> O. W. Holmes

As his letter shows plainly, Holmes knew that he was suggesting, in "anaesthesia," a word already known to medicine. He proposed an enlargement in the definition of the word, which still is used both to indicate insensibility of touch and to identify the process of general anesthesia. A modern analogy to this method of naming might be the application of "memory" to the guiding principle of genetic replication. A well-known and commonly used word has been broadened in a clearly defined way. This flexibility is a strength of English—so long as definitions are well stated and equally well understood.

And Holmes' role? It would seem to have been less inventive than common mythology would have it, but seminal all the same. And so, even though all this talk of words might conceivably have anesthetized you, it didn't hebetize you.

Regards,



[Charles G. Roland, M.D.]

An Evaluation of Memory Under Regional Anesthesia with IV Lorazepam as a Premedicant

HARVEY A. TAUB, PhD*
LOUIS EISENBERG, MD†
Syracuse, New York

Forty male volunteer patients undergoing regional anesthesia were evaluated for alertness and memory in a double-blind study which compared IV lorazepam‡ (4 mg) plus IM meperidine (50 mg) with IV placebo plus IM meperidine (50 mg) as premedicants. The data indicate no significant retrograde effects. Significant differences at all measurement points from 20 minutes to 3 hours following IV drug administration indicated greater sedation and less recall and recognition of events and stimuli (auditory and visual) with the combination of lorazepam and meperidine than with placebo and meperidine. A significant number of patients over age 40 were judged to be excessively sedated after administration of lorazepam. However, respiration, blood pressure, and pulse did not appear to be differentially affected by lorazepam and there were no adverse changes even in patients considered to be oversedated.

NUMEROUS reports have called attention to the desirability of having a premedicant that not only provides sedation but also reduces or eliminates recall of the surgical experience.[1-4] The effects upon memory of the benzodiazepine tranquilizer, diazepam, are well documented, with maximum effects lasting for up to 20 to 30 minutes after IV administration.[2,5,6]

Recent studies suggest that a new benzodiazepine derivative, lorazepam, may be a more potent sedative and have longer-lasting effects upon memory than diazepam.[7-9] The present experiment was designed to provide an extensive evaluation of memory following IV lorazepam premedication for regional anesthesia. Lorazepam and meperidine were compared with placebo plus meperidine in a double-blind evaluation. Stimuli were presented before, during, and after the operative procedure, and memory for these materials was evaluated on the following day.

METHOD

Patient Selection and Anesthetic Procedures.—Forty male volunteers, scheduled to have regional anesthesia for elective surgery, and who met the criteria of having no psychiatric disorders, sensitivity to benzodiazepines or to the glycol base of the drug, or severe visual or auditory impairments, gave written informed consent for participation in the study.

All patients received 50 mg of meperidine and 0.4 mg of atropine IM in their hospital room approximately 1 hour before their operation and were then brought to a holding area (recovery room) where they received the test drug IV. Approximately 20 minutes after IV administration, they were

This study was performed as part of Veterans Administration Research Project No. 2255-01. It was supported in part by a grant from Wyeth Laboratories, Philadelphia, Pennsylvania.

Paper received: 10/14/75

Accepted for publication: 11/17/75

taken into the operating room. For half the patients, the IV test drug consisted of 4 mg of lorazepam in a glycol base, while the rest received a placebo (glycol base only). The use of identical syringes and prearranged random orders permitted a double-blind procedure so that neither the physicians nor the patient knew whether lorazepam or placebo had been administered. Each identical 2 ml syringe was prepackaged to be half full of lorazepam or placebo and was diluted with an equal volume of saline solution prior to use.

Analysis of patient characteristics and surgical procedures after the code was broken indicated that the random and blind assignments produced groups that were equated. There were no differences in age or weight (table 1), type of operative procedures (table 2), or length of operations (89.6 min for lorazepam versus 91.7 min for placebo). Physical status was similar, and in both groups approximately 50% of the patients were in each of the ASA ratings of I and II. Seventeen patients (85%) in each group underwent surgery with spinal anesthesia, the rest receiving either an epidural (n=2) or an IV block (n=1).

One patient in the placebo group was excluded from further participation in the study, since a proper level of spinal anesthesia could not be attained and general anesthesia had to be administered. Thus, the placebo group was reduced to 19 for the remainder of the study. Two additional placebo patients received supplementary meperidine (40 mg), N_2O (70%), and either halothane (n=1) or methoxyflurane (n=1) near the middle or end of the surgical procedure. The data for these patients have been included, since these additional anesthetics were administered after the surgical portion of the memory stimuli were presented and since they did not appear to affect the scores.

MEMORY TESTING PROCEDURES

Stimuli.—Both visual and auditory stimuli were used. The visual stimulus was a 10 x 25-cm picture of a dollar bill. The auditory stimuli consisted of 3 different word-pairs (eg, furniture—chair) and 3 different sounds (eg, a fire engine) which were taped in an alternating pattern starting with a word-pair (stimulus 1) and ending with a sound (stimulus 6). To reduce the possibility of bias from specific stimuli, 2 completely different tapes were constructed.

Both stimulus tapes contained a 1-minute volume adjustment section ("testing, 1, 2, 3") which preceded the 6 alternating word-pairs and sounds. Each stimulus presentation period was also approximately 1 minute long. For any particular word-pair presentation, the stimulus was first identified and then was repeated 3 times. For each sound presentation, the stimulus was identified 4 times by name and then played for 20 seconds. After each stimulus, the patient was requested to repeat aloud the words or to name the sound, to demonstrate that he heard the material.

Each stimulus was used to evaluate memory during a different portion of the surgical experience. Stimulus 1 evaluated possible retrograde effects and was presented approximately 3 minutes before administration of the IV test drug. Stimuli 2-5 were presented in the operating room and were designed to evaluate memory during the first 90 minutes after administration of the test drug. They were presented at successive 20 to 25-minute intervals: stimulus 2, before administration of the regional anesthetic; stimulus 3 before incision; stimuli 4 and 5 during the early portions of the surgical procedure. Stimulus 6 evaluated memory after completion of the operation and was presented when the patient was ready to be dismissed from the recovery room. The visual card was shown immediately before stimulus 2. Table 3 shows actual mean time relative to the test drug that the stim-

uli were presented to each of the groups. Analyses of variance revealed no statistically significant differences in these times.

Instructions and Procedures.—Following the preanesthetic examination, volunteers were interviewed and given instructions by a research technician (experimenter 1). All were informed about the type of stimuli they might receive and instructed to try to remember as much as possible about the surgical events.

On the day of operation, a second research technician (experimenter 2) met the patient in the holding area, provided further instructions, placed the earphones, established a comfortable volume level, presented both the visual and auditory stimuli at the appropriate times, rated the patient for alertness at each stimulus presentation, and interviewed him on leaving the recovery room. Alertness at each stimulus presentation was rated on a 5-point scale, with the following descriptive range:

1. Highly alert
2. Alert
3. Drowsy
4. Light sleep
5. Deep sleep

Experimenter 1, without knowledge of tape assignments or alertness ratings, interviewed each patient approximately 24 hours after the operation. The interview included standard questions about surgical and recovery room events, a patient rating of the test drug, and measurement of recall and recognition of visual and auditory stimuli. For visual recognition, the dollar bill was presented along with 7 other familiar pictures (eg, postage stamps); for the auditory task, recognition was evaluated using a composite tape which, for each patient, consisted of the stimuli intermixed with 6 additional word pairs and 6 additional sounds. In both cases, the patient was asked to indicate if he recognized any of the stimuli as having been presented on the day of operation.

RESULTS

The frequency of *yes* (recall, recognition) and *no* (no recall, no recognition) responses of the 2 groups was compared by chi-square analysis. Summary of the recall and recognition data (table 3) indicates that both groups performed at a high level and did not differ in their memory of stimulus 1. Since this stimulus was presented before the test drug, the lack of difference suggests that lorazepam did not have a retrograde effect upon memory. All other group comparisons of recall and recognition, except one, achieved statistical significance, indicating that lorazepam affected memory within 20 minutes after IV administration and that, in general, this effect persisted throughout the total measurement period of more than 3 hours. Although there were some differences in actual scores, these findings were consistent for both the visual (dollar bill) and auditory (stimulus 2) stimuli, suggesting that the loss occurred with both modalities.

*Difference between lorazepam and placebo groups significant at $p<0.01$.

†Difference between lorazepam and placebo groups significant at $p<0.05$.

Table 3 also illustrates that estimates of memory may vary as a function of both the type of stimuli and type of measurement. Recall, especially of words, was less reliable than recognition and may be a poorer estimate of memory in the complex surgical situation where even the placebo patient may be distracted by other, more relevant, events. In addition, the recognition scores appeared to be similar to those obtained for memory of relevant events (eg, entering OR, testing anesthesia with a needle, leaving recovery room). There were significant group differences in all chi-square comparisons ($df=1$) of memory for relevant operating-room events, with 89 to 100% of the placebo patients having a recall of these events as compared to only 28 to 50% of the lorazepam patients. Again, these differences persisted until the patient left the recovery room.

The effects obtained with alertness ratings were similar to those exhibited for memory. There were no group differences in the holding area (stimulus 1) before administration of the test drug, and patients generally were awake and lightly sedated ($\bar{x}=1.9$ for lorazepam and 1.7 for placebo). While ratings were not taken between stimuli 1 and 2, observation of patients suggests that the sedative effect of lorazepam began almost immediately after IV administration and that many were drowsy or fell asleep within 5 to 10 minutes.

Highly significant group differences were found for all measurements after administration of the test drug ($p<0.01$), beginning in the operating room with stimulus 2 ($\bar{x}=3.3$ for lorazepam and 1.8 for placebo) and continuing through recovery with stimulus 6 ($\bar{x}=2.6$ for lorazepam and 1.5 for placebo). During the interval from stimulus 2-5, 70 to 80% of the lorazepam patients were drowsy (rating 3) or asleep (ratings 4 and 5) and 40 to 55% were too sedated or disoriented to repeat the stimuli when they were presented. This did not appear to affect the overall conclusions about lorazepam and memory, since further analysis suggested that the loss in recall and recognition was similar, whether or not the stimulus could be repeated during the operation.

Consistent with but more important than the alertness rating results was the finding that significantly more lorazepam patients (n=6) than placebo patients (n=0) were considered to be oversedated ($\chi^2=4.62$, $df=1$, $p<0.05$). Five of these lorazepam patients were rated unsatisfactory by the anesthesiologist, while the sixth was rated satisfactory but considered to be borderline. In all these cases, the patient was judged to be so deeply sedated that it was difficult to judge the level of regional anesthesia. None responded to verbal commands when tested for sensory levels. Four responded only with general reflex movements, while 2 were completely obtunded and gave no response at all. Even though these patients were markedly sedated, respirations were deep and adequate, none requiring ventilatory assistance.

Lorazepam incidentally appeared in these studies to have little effect upon the cardiovascular system (table 4). Measurements of pulse and blood pressure taken before administration of the test drug, upon entering the operating room, after the regional anesthesia, and in the recovery area indicated no significant differences between the 2 groups.

Patient ratings of the test drugs indicated a group difference ($\chi^2=9.84$, $df=3$, $p<0.05$), with all lorazepam patients rating the premedication as excellent or good as compared to 74% for the placebo. Two (10%) of the placebo patients rated the test medication as only fair, and 3 (16%) considered it to be poor.

Numerous post-hoc evaluations of the lorazepam data attempted to determine the factors that might differentiate between the sedated and oversedated patients. While

TABLE 4
Mean Values for Blood Pressure and Pulse Rate

Measurement	Systolic (mmHg)		Diastolic (mmHg)		Pulse rate (per/min)	
	Lorazepam	Placebo	Lorazepam	Placebo	Lorazepam	Placebo
Predrug	127.7	129.2	80.3	79.5	79.4	76.7
Enter operating room	128.8	135.0	78.8	81.8	80.4	78.8
Regional	124.8	130.0	72.5	77.4	81.5	80.7
Recovery	121.8	122.2	72.7	73.8	76.4	72.9

weight suggested a possible trend, the only significant factor was age ($\chi^2=5.95$, $df=1$, $p<.0.05$). All 6 of the patients judged as oversedated were among the 10 patients between the ages of 46 to 63 years, while this condition was not found in any of the 10 patients between ages 23 to 26. Further comparisons of age within the lorazepam group suggested differences only for alertness ratings, with no differences in memory, body weight, blood pressure, pulse, pulse pressure, length of operation, or length of stay in the recovery room.

DISCUSSION

The combination of meperidine (50 mg) IM and lorazepam (4 mg) IV led to heavier sedation and less recall and recognition of events and stimuli than meperidine IM with placebo. These differences persisted throughout the whole measurement period of approximately 3 hours and, for at least some patients, may have continued into the night of surgery. These suggestions of long-lasting effects are consistent with previous reports on the use of lorazepam as a premedicant[7,8] and suggest that its effects are more persistent than those noted with even higher doses of diazepam.[2,5,6] In addition to these positive findings are the suggestions that respiration, blood pressure, and pulse were not differentially affected by lorazepam and that there were no adverse changes even when patients were considered to be oversedated. These suggestions are consistent with previous reports on the use of IM lorazepam.[8]

The finding of excessive sedation with patients over age 40 was not predicted from either our own preliminary pilot work with 4 mg (unpublished) or from a study by Heisterkamp and Cohen,[7] which used 5 mg IV lorazepam as a premedicant for regional anesthesia. However, it is difficult to make comparisons across these studies, since the mean age of patients in our pilot project was 26.2 years (n=5) and since Heisterkamp and Cohen[7] did not provide the ages of their patients (n=5).

In view of the current findings and the lack of comparable data, we performed 2 additional pilot evaluations in patients 40 years of age or over, to (a) determine whether a lower fixed dose might be adequate, and (b) evaluate the use of a weight-related dose. The first pilot study evaluated 2 mg (n=3), 3 mg (n=4), and 4 mg (n=4), but was discontinued when the 2-mg dose did not appear to provide sufficient sedation and 1 patient in each of the other groups (3 and 4 mg) was oversedated. In the second study (n=9), using a dose of .044 mg/kg rounded to the nearest 0.5 mg, 2 patients were also considered to be oversedated.

While there were not enough cases for statistical analysis of these pilot studies, one may speculate from the combined data that the desirable dose level may be close to .044 mg/kg. Unsatisfactory ratings were given to 2 of 4 patients who received more than .048 mg/kg, 2 out of 8 patients who received between .042 to .048 mg/kg, and 0 out of 8 patients with lower dose levels, suggesting that values above .044 mg/kg may increase the chances of oversedation.

On the other hand, values below .044 mg/kg may have a reduced effect upon both sedation and memory. None of the 9 patients receiving doses above .044 mg/kg recalled any stimuli, while of the 11 receiving less than this value, 4 recalled stimulus 2. Two of these latter patients also recalled 1 or more later stimuli. This suggests that limits around .044 mg/kg may be very narrow for individuals above age 40 and, more importantly, indicates the need for additional research to establish a useful dose level for all age groups. Studies are needed both with and without the use of meperidine, since the finding of excessive sedation in older patients may be due to the combined effects of meperidine with lorazepam.

In conclusion, this study indicates that lorazepam may be useful and safe to use as a premedicant, especially when the surgical procedure is prolonged, and that it may be readily accepted by patients. Although the drug may have no retrograde effect upon memory, and even though patients may appear to be awake, it significantly reduces recall and recognition of events for as long as 3 hours after a single IV injection. However, because of its powerful and persistent sedative effects, further research is necessary to determine useful dose levels and to establish the possible drug interactions between this benzodiazepine tranquilizer and narcotic analgesics.

ACKNOWLEDGMENT

The authors wish to thank Marilyn Baker and Gary Kline of the Psychology Service, Veterans Administration Hospital, for their valuable assistance in all phases of this study.

ANTIEMETIC EFFECT OF THC Oral delta-9-tetrahydrocannabinol (THC) was compared with a placebo as an antiemetic for nausea and vomiting following cancer chemotherapeutic drugs. Oral THC (10 mg/m^2) was an effective antiemetic in 14 of 20 courses while the placebo was ineffective in all instances. The lack of THC effect in some patients may be related to failure of gastrointestinal absorption. No patient vomited while experiencing a "high" from THC. Although somnolence often occurred with this THC dose, a significant curtailment of activities was infrequent. Toxicity (fear, panic, hallucinations) occurred in only two patients, both after three THC doses of 20 mg. *(Sallan SE, Zinberg NE, Frei E: Antiemetic effect of delta-9-tetrahydrocannabinol in patients receiving cancer chemotherapy. Analysis of Tasks and Human Factors in Anesthesia for Coronary-Artery Bypass

PETER J. KENNEDY, MS*
ALFRED FEINGOLD, MD†
EARL L. WIENER, PhD‡
RONALD S. HOSEK, PhD§
Miami, Florida‖

A comprehensive task analysis of the anesthetist's activities during coronary-artery bypass procedures was carried out using time-lapse cinematography. This film was analyzed frame by frame to detect types of activities and the proportion of time spent on each. Link analysis was used to reveal recurring sequences of activities. Of the 9 activity categories, the anesthetist spends the greatest portion of time observing the patient and scanning the entire operative and monitoring field. Ten to 15% of the time is spent logging data on the anesthetic record. The challenge for the anesthetist is to optimize his performance, and those under his direction, in the face of the changing workload resulting from variations in patients' conditions. Use of an automated monitoring system that charts patient vital signs would allow the anesthetist to apportion this time among other tasks.

THE functions of anesthetists are subject to extreme fluctuations. A task analysis during coronary-artery bypass, employing time-lapse cinematography, was undertaken to reveal the extent to which total activity and particular duties fluctuate during anesthesia.

METHODS

The time-lapse cinematography used the following equipment: 16 mm camera (Bell and Howell, model 70-DR) equipped with a custom-made synchronous motor and Geneva drive (Lafayette Instruments Company, model 5406); Kodak Ektachrome 7242 emulsion EF type B 449, ASA 125, which permitted exposure under ambient illumination. The camera equipment was located outside a window of the operating room, as unobtrusively as possible.

Preliminary studies showed that the anesthetist is involved in virtually no activities completed in less than 2 seconds and, therefore, an interframe interval of 2 seconds was acceptable.[1] Detailed activity was subjected to frame-by-frame analysis.

Transcription of the data from film to workable form was facilitated by entering the data directly into a computer keyboard (PDP-12) while viewing the films. The computer program then performed a number of calculations including the tally of elapsed time, man-minutes per activity code, and link analysis. The rate at which the films were reviewed was approximately 2000

frames (1 hour's surgical operative time) in an 8-hour day. Initial analysis of the films established 13 categories of anesthetists' activities[2]; this was subsequently reduced to 9 categories (table). In 5 of these, the anesthetist's attention is directed toward, in 3, away from, and in 1, both toward and away from the patient-surgical field.

Three elective coronary-bypass procedures lasting 6, 8, and 9 hours were studied in the context of a teaching hospital where surgical anesthesia and operations were performed by residents and faculty. The procedures were divided into 3 phases: (1) prepump, wherein the patient is prepared, anesthesia is induced, thoracotomy is performed, and the pump tubing is connected; (2) on-pump, during which the respirator is shut off and circulatory bypass is effected; and (3) post-pump, during which the patient's heart is defibrillated and the surgical procedure is completed.

RESULTS

Figure 1 is an overview of the activities for case 1. The abscissa represents the elapsed time in hours. The ordinate scale is

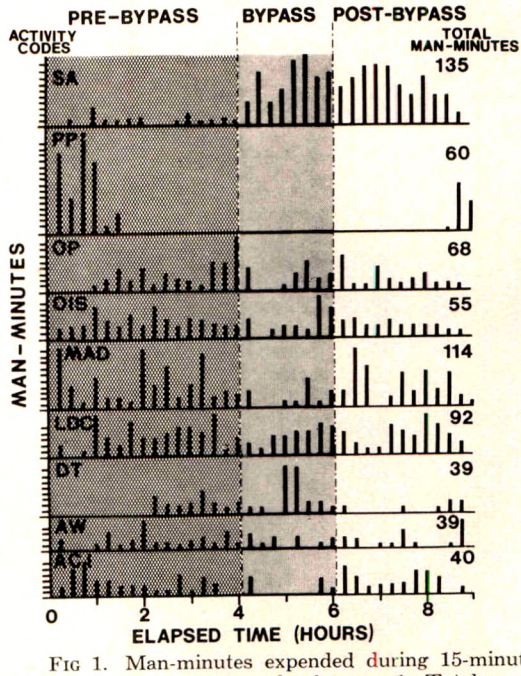

FIG 1. Man-minutes expended during 15-minute intervals on 9 activity codes for case 1. Total man-minutes is the sum of the man-minutes expended on an activity code. Symbols are defined in the table.

TABLE
Activity-Code Symbols

Symbol	Description	Attention*
ACI	Adjust or calibrate instrument (respirator, heating blanket, IV)	T & A
AW	Arrange equipment (instruments, table)	A
DT	Data transfer: anesthetist communicates or gestures to another person	A
LDC	Log data on anesthetic record or read chart	A
MAD	Mix or administer drugs	T
OIS	Observe oscilloscope or other monitor	T
OP	Observe patient (skin color, surgical field, etc.)	T
PP	Prepare patient (place ECG leads, BP, transducers, etc.)	T
SA	Scan area (attention not directed to any instruments or display but scanning entire field)	T

*"T" indicates that the anesthetist's attention is directed *toward* the patient-surgical field. "A" indicates that the anesthetist's attention is directed *away* from the patient-surgical field.

repeated once for each activity code and represents the man-minutes expended during 15-minute intervals on that activity code. The number at the extreme right of each activity represents the total time in man-minutes for that activity. The sum of the total man-minutes for each activity code agreed closely with or exceeded the elapsed time.

At the beginning of the procedure, the anesthetist attached monitors, induced anesthesia, and intubated the patient; this is reflected (fig 1) by an initial peak of the activity code, prepare patient (PP). At the end of the case, another peak of PP occurs, indicating the preparations prior to transporting the patient to the postsurgical recovery unit. During bypass, some activities drop to a low level. The principal exceptions to this appear to be scan area (SA), and data transfer (DT).

Figure 2 summarizes the percent of the anesthetist's time expended on each activity code for the 3 cases. This summary is arranged in order of increasing time expended.

Sequences of activities which recur throughout the procedure were revealed by link analyses. A 9 x 9 matrix of the present

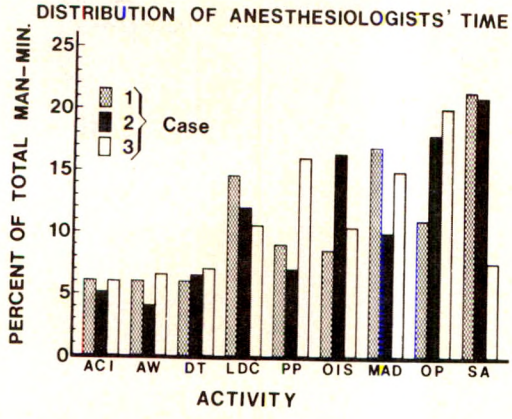

FIG 2. Percent distribution of anesthetist's time for the 3 cases. Symbols are defined in the table.

activity and the next activity was constructed. By dividing each present activity entry by the total of the corresponding present activity column and multiplying by 100, the table is normalized. For example, logging data (LDC) follows observing monitors (OIS) 51% of the time. If the present activity is OIS, there is a 9% probability that the next activity will be to observe patient (OP).

DISCUSSION

Few studies have applied quantitative measures to obtain data that can be used to improve the human factors in the practice of anesthesiology. Photographic time studies were pioneered by Gilbreth,[3] who proposed standards for some procedures. More recently, Drui and associates[4] used time-lapse cinematography to study 8 cases, including one 10-hour cardiac surgical procedure, for a total of 26 hours of study. Using 24 separate activity codes, they found that the largest amount of time was spent in filling out the anesthetic record and that 46% of the anesthetist's time was spent looking away from the patient-surgical field.

Our data support many of their observations and conclusions. Figure 2 shows that the anesthetist spends 8 to 22% of his time scanning the area (SA), 11 to 22% observing the patient (OP), 10 to 17% mixing or administering drugs (MAD), 8 to 17% observing monitors (OIS), 7 to 16% preparing the patient for anesthesia and transfer (PP), 10 to 15% logging data or reading chart (LDC). The time spent looking away from the patient-surgical field on other essential tasks may include the categories LDC, DT, AW, ACI, and amounts to 28 to 33% of the total man-minutes.

The anesthetist's primary tasks are to observe the patient, observe monitoring equipment, and continuously review his options of drugs and dosage. Superimposed upon these are a variety of secondary tasks, such as fluid replacement, preparation of supplies, and updating the clinical record.

Like Drui's group, we found the placement of equipment and displays in the operating rooms was haphazard. In two institutions, the multichannel oscilloscope was behind the anesthetist, requiring a body movement for the OP→OIS sequence. Although this location is convenient for the surgeons, relocation of the oscilloscope would reduce body movements of the anesthetist.

Link analysis showed that OIS, SA, and MAD are followed by logging data (LDC) 51%, 46% and 37% respectively. OIS follows LDC, OP, MAD, and PP 43%, 33%, 34% and 33% respectively. These data further emphasize the importance of proper arrangement of the equipment in the patient-surgical field.

Our results show that periodic transcription of patient data to the anesthetic record (LDC) requires 10 to 15% of the anesthetist's time. An automated system for charting the patient's vital signs would allow the apportionment of this time among the remaining tasks. In addition to logging vital signs, a computerized system could produce a more complete and accurate record than a manual system. Additional information available from the ECG could be computed, displayed, and recorded. The computer-produced record might also provide useful information for postoperative studies.[4]

Our observations suggest that any automated system should include a properly placed oscilloscope display. Additional functions should be added to the display to show trends and allow a comprehensive clinical picture of the patient's status with only limited eye movement by the anesthetist.

Improved patient care can follow if human-factors and systems specialists study anesthetic procedures and identify error-producing aspects resulting from the interaction between the anesthetist and his equipment. The collection and analysis of design-induced errors, perhaps using the method described by Fitts and Jones[5] to study design-induced pilot errors, could lead to the identification of recurring problems, which could then be designed out of the anesthesia man-machine systems.

AWAKE DURING OPERATION Awareness during anesthesia and operation may result in a traumatic neurotic syndrome. The authors describe such a syndrome in six patients characterized by 1) recurrent nightmares, 2) irritability, 3) a preoccupation with death, and 4) reluctance to describe symptoms to physicians for fear they would be misinterpreted. In all six cases a direct explanation to the patient that they indeed were "awake" during the operation served as a dramatic cure. The incidence of such occurrences may be underestimated due to patient reluctance to discuss their symptoms. *(Blacher RS: On awakening paralyzed during surgery. A syndrome of traumatic neurosis. Anesthetic Considerations for Pericardectomy in Uremic Pericardial Effusion

HALAPPA N. KONCHIGERI, MD*
SIDNEY LEVITSKY, MD†
Chicago, Illinois‡

Fifteen patients with impending uremic cardiac tamponade underwent either anterior pericardectomy or pericardiostomy under general anesthesia. Anesthetic agents and technics were selected in the light of physiopathologic derangements involving fluids and electrolyte balance, excretory and cardiovascular disturbances, and pharmacodynamics. Anesthesia was induced with diazepam and maintained with N_2O-O_2 (70:30) and fentanyl. Pancuronium was used for muscle relaxation. Adequate preoperative assessment of patient, careful monitoring of vital signs, maintenance of the critical balance of fluid and blood replacement, and selection of anesthetic agents for minimal depression of vital multiorgan systems provided excellent results. No postanesthetic morbidity or mortality occurred.

ALTHOUGH pericarditis associated with uremia has been known since 1836,[1] cardiac tamponade in this condition was first documented only in 1956.[2] This potentially dangerous condition has been reported in patients both before and after beginning maintenance hemodialysis. Cardiac tamponade has been observed in 2.6 to 6% of patients in renal failure and 15 to 55% of uremic pericarditis cases.[3] The increasing incidence is considered due to the prolongation of life of uremic patients by maintenance dialysis.

The recommended treatment for uremic pericardial effusion with tamponade is aggressive dialysis, repeated pericardiocentesis, creation of a pericardial window, or partial pericardectomy. Based on current data, partial pericardectomy has been strongly advocated as the definitive treatment of uremic pericardial tamponade.[4]

In the anesthetic management, the anesthesiologist is faced with the basic problems of chronic renal failure[5] compounded by the changes in cardiovascular hemodynamics brought by the uremic cardiac tamponade. This presentation describes special anesthetic problems and our experience in the anesthetic management for either pericardiostomy or anterior pericardectomy (phrenic-to-phrenic) in patients with uremic pericardial effusion and constriction.

MATERIALS AND METHODS

Fifteen patients with uremic pericardial effusion and clinical signs of impending tamponade underwent either anterior pericardectomy (12 patients) or pericardiostomy (3 patients) under general anesthesia. Patients, 10 males and 5 females, ranged in age from 15 to 66 years (average 31). All except 1 (class IV) were of ASA physical status III.

Preoperative Evaluation.—Most patients were underweight, undernourished, and mentally depressed. Predominant physical

findings were tachypnea (>25/min), tachycardia (>100/min), temperature elevation of 1 to 3° F above normal, elevation of central venous pressure (CVP) (>15 cm H_2O), and mild to moderate degrees of hypertension. There was increased cardiac dullness on percussion and bilateral basal moist rales on auscultation in the majority. Patients were receiving multiple medications, including methyldopa, digitalis, furosemide, azothioprine, prednisone, antibiotics, and supplemented iron therapy.

Laboratory Data.—Preoperative hematologic and biochemical data (table 1) showed polymorphonuclear leukocytosis in 12 patients. Platelet count (carried out in 10 patients) was reportedly normal. Chest roentgenography revealed progressive cardiomegaly in all patients. Electrocardiographic abnormalities included left ventricular hypertrophy with strain (5 patients), nonspecific ST-T wave changes (2 patients), junctional rhythm (2 patients), atrial flutter with 3-to-1 block (1 patient), and sinus tachycardia (several patients).

All patients were on regular maintenance hemodialysis, 2 or 3 times a week, before hospitalization. Intensive medical management of pericardial effusion involved daily hemodialysis and pericardiocentesis. Surgical intervention was considered necessary only in those patients who exhibited radiographic evidence of enlarging cardiac silhouette, accompanied by: (1) signs of cardiac embarrassment (arrhythmias and hypotension), (2) elevated CVP and/or paradoxical pulse pressure of 15 to 20 torr, (3) negative response to aggressive hemodialysis, and (4) echocardiographic evidence of increased accumulation of pericardial fluid.

Premedication.—Five patients received 5 to 10 mg of diazepam IM, approximately 1 hour before anesthesia, while the remainder received no premedication.

Anesthetic Management.—Baseline readings of vital signs (temperature, respiratory rate, pulse rate, blood pressure, ECG and CVP) were recorded. The usual sterile surgical preparation and draping were carried out while the patient received O_2 by face mask before induction of anesthesia.

Anesthesia was induced with diazepam, administered in incremental doses of 5 mg (total dose 10 to 25 mg) until optimal sedation was reached without untoward effect on vital signs. Pancuronium (0.1 mg/kg) was administered to facilitate endotracheal intubation. Anesthesia was maintained with 70% N_2O in O_2 and supplemented with minimal doses of fentanyl. Ventilation was controlled in all patients throughout the surgical procedure, and arterial blood gas was measured intraoperatively in 8. Midline sternal splitting incision was used for thoracotomy in patients scheduled for anterior-pericardiectomy, which involved removal of anterior pericardium between the phrenic nerves as well as excision of the pericardial reflections around the venae cavae, and a subxiphoid incision was used for pericardiostomy.

At the termination of the procedure, the residual effect of pancuronium was reversed by administering 5 mg of prostigmine and 1.2 mg of atropine in a premixed solution. Patients were extubated either in the operating room or in the cardiac surgical intensive care unit after assessment of vital signs and adequacy of ventilation.

Intraoperative Monitoring.—In addition to the usual parameters (temperature, pulse, respiration, blood pressure, and tidal volume), CVP was measured in 6 patients, and intraarterial blood pressure, by placement of a catheter in the dorsalis pedis artery, in 4 patients.

Intravenous Fluids.—Patients received 200 to 1400 ml (average 680 ml) of 0.45%

TABLE 2
Pulse-Rate and Blood-Pressure Changes During Anesthesia and Recovery

	Pulse (Mean ± SD)	Blood pressure (Mean ± SD)	
		Systolic	Diastolic
Preinduction	101 ± 13	134 ± 29	81 ± 12
Induction	102 ± 13	142 ± 29	83 ± 16
Maintenance	107 ± 10	142 ± 25	85 ± 10
Recovery	99 ± 9	139 ± 21	83 ± 7

None of the parameters measured were statistically significant at $p < 0.05$.

normal saline solution in 5% dextrose and/or lactated Ringer's solution in 5% dextrose solution to replace serosanguinous fluid loss. Ten patients were given 1 to 4 units of triple-washed red blood cells intraoperatively.

RESULTS

Duration of the surgical procedure ranged between 70 and 300 minutes (average 143 minutes). Variations in either heart rate or blood pressure during anesthetic induction, maintenance, or recovery were not statistically significant (table 2) except in 1 patient, in whom there was a transient bradycardia (heart rate 50 to 55/min) during cardiac manipulation; this was promptly treated with IV administration of atropine. During dissection of a thick epicardial peel, a second patient developed premature ventricular contractions (PVCs) of 2 to 5/min; intervals of rest during the procedure improved the cardiac rhythm without the need for further therapy. Central venous pressure decreased by 3 to 10 cm H_2O as the chest and pericardial sac were opened. Average intraoperative blood-gas measurements were: Pao_2, 121 torr (111 to 150); $Paco_2$, 32.2 torr (27 to 38); pH, 7.49 (7.41 to 7.53); HCO_3, 24.9 (19 to 28).

Anesthesia provided highly satisfactory operating conditions, and all patients showed rapid recovery, complete amnesia, and a benign postanesthetic course. No postoperative mortality or morbidity was related to the anesthetic management.

Echocardiography.—Ultrasound scanning has been shown to be accurate, safe, and reliable for detecting pericardial effusion, and can be conducted at the bedside in a few minutes without patient discomfort.[6] Echocardiography is based on a simple principle: When ultrasound, passing through an acoustically uniform medium, reaches the interface with a medium of different acoustic impedance, some of the waves will be reflected back (echoes) to the transducer, while the remainder of the energy is transmitted into the second medium.[7] When an ultrasound transducer is placed along the left sternal border in the 4th or 5th intercostal space and facing posterolaterally, the ultrasonic beam will traverse the anterior chest wall and various structures of the heart to the posterior mediastinum and lung. Reflected ultrasonic energy (echoes) from the different media are recorded on the self-developing film of an ultrasonoscope. Pericardial fluid is recorded as echo-free space between the posterior left ventricular epicardium and the posterior pericardium. Anterior fluid is seen as a similar echo-free space between the anterior right ventricular wall and the anterior chest wall.[6]

DISCUSSION

Patients with uremic pericardial tamponade present complex homeostatic disturbances involving multiorgan systems. Chronic renal failure is associated with severe anemia, hypoproteinemia, chronic azotemia, and electrolyte disturbances. Although biochemical disturbances can be largely corrected by hemodialysis, emergency surgical procedure may require anesthetic administration in a patient with extreme biochemical disturbances. Decreased resistance and increased susceptibility to infection necessitates a meticulous aseptic technic and, frequently, antibiotic administration. The possibility of interaction between medications (antibiotics, immunosuppressive and antihypertensive agents, digitalis, diuretics) and anesthetic agents must be considered.

A majority of such patients are hypertensive and have associated cardiomegaly, conduction defects, atherosclerotic vascular changes, and uremic cardiomyopathy. In addition, patients are susceptible to serous effusion in peritoneal, pleural, and pericardial cavities.

Pericardial effusion produces several major hemodynamic changes. Cardiac tamponade limits diastolic expansion of heart chambers, increases intraatrial, intraventricular, and pericardial pressures, and leads to decreased stroke volume and cardiac output.[8,9] Left ventricular function has been shown to be depressed by significant falls in ejection fraction and mean ejection rate.[9] Increased pressure in both atria is reflected in a marked rise in pulmonary and systemic

venous pressure. During cardiac tamponade, cardiac output can be increased by expansion of total blood volume at the expense of raised central venous pressure.[10] There is a decrease in coronary blood flow, while myocardial metabolic O_2 demand is greatly increased as a resultant of tachycardia. Coronary blood flow may be critically affected by changes in coronary vascular resistance, heart rate, arterial pressure, and cardiac output.[11]

In patients with cardiac tamponade, cardiac output is reduced and therefore requires increased venous filling pressure; hence, anesthetic agents causing marked depression either of myocardial contractility or peripheral vascular resistance (PVR) should be used with great caution.[12] Monitoring of the CVP assists greatly in maintaining adequate fluid administration. Also, because of the increased incidence of cardiac arrhythmias in patients with tamponade, ventilation and oxygenation should be well maintained. Increased intrathoracic pressure due to straining or coughing during induction, or to overly vigorous controlled ventilation, may result in further tamponade of the heart and intrathoracic veins, causing more hypotension.

Surgical removal of pericardium adherent to the pericardial surface may involve meticulous dissection, leading to considerable blood loss. Manipulation of the heart may greatly upset circulatory dynamics and precipitate hypotension or arrhythmias to the extent of ventricular fibrillation. Close monitoring of the cardiovascular system, gentleness in the surgical procedure, and adequate fluid and blood replacement are all essential for successful patient management.

Anesthetic Agents.—Reduced tolerance to the depressing effect of drugs and unstable cardiovascular dynamics in uremic pericardial tamponade warrant elimination or minimizing of the dosage of potent sedatives and narcotic premedicants. Thiopental induction is risky in patients with tamponade,[13] while diazepam has reportedly proved to be an excellent induction agent, with negligible cardiovascular depression, good anterograde amnesia,[14] and enhanced coronary blood flow through vasodilation.[15]

Halogenated inhalation anesthetics produce significant myocardial depression and peripheral vasodilation.[16,17] Although sympathomimetic effects of cyclopropane and diethyl ether are beneficial in maintaining PVR,[17] routine use of electric bone saws and other electric instrumentation excludes these agents from consideration. Ketamine, with no significant effect on PVR in patients with chronic renal failure,[18] may be considered useful. Morphine can produce significant decrease in systemic arterial resistance, vasodilation, peripheral pooling, and reduced venous return to the heart.[19] Administration of drugs with alpha or beta-blocking properties (droperidol, thorazine, phenoxybenzamine, phentolamine, propranolol) may be lethal in these patients. Because of the negligible effect of pancuronium on the cardiovascular system,[20] this drug was included in our anesthetic management.

Some authors[12] have advocated the technic of local infiltration and sedation for subxiphoid pericardiostomy. The disadvantages of this method are: (1) a large volume of local anesthetic may produce significant myocardial depression; (2) if the operative procedure is extensive, intraoperative anesthesia may be required; (3) synergistic action of the local and general anesthetic agents may produce cardiovascular depression.

Special attention must be paid in the proper care of A-V fistula in the arm, aseptic anesthetic technics, and adequate protection of pressure points on patient positioning. Radial artery and veins at the wrist are to be spared cannulation whenever possible, so that they can be used for a later A-V fistula. Dorsalis pedis artery puncture or cannulation can be used for obtaining blood-gas measurement and arterial pressure recordings.

In our present experience, adherence to the outlined principles of anesthetic management for pericardectomy has produced excellent results with no operative or anesthetic related mortality or morbidity.

ADDENDUM

Since this paper has been submitted for publication, pericardectomy has been done in three more patients with good results without any related sequelae.

Effect of Isoproterenol and Propranolol on Halothane MAC in Dogs

YASUMASA TANIFUJI, MD*
EDMOND I. EGER, II, MD†
San Francisco, California‡

To evaluate the effect of propranolol on anesthetic requirement, changes in minimum alveolar concentration (MAC) of halothane accompanying acute (2 and 10 mg/kg IV) and chronic (200 mg/day orally for 10 days) propranolol administration were determined in dogs. MAC did not change significantly in either case. Beta-adrenergic blockade was achieved with the 2 mg/kg propranolol dose, as indicated by abolition of the pulse rate increase in response to isoproterenol infusion. Isoproterenol itself did not alter MAC. Mean arterial pressure (MAP) and heart rate (HR) at any given level of alveolar halothane were the same before and after chronic propranolol administration. Acute IV administration of propranolol, especially at the 10 mg/kg dose, reduced MAP and increased HR only transiently.

PROPRANOLOL is used extensively for beta-adrenergic blockade in the treatment of angina,[1,2] and for hypertension.[3] It also has been used to treat arrhythmias during anesthesia. Several reports suggest that propranolol may be depressant in animals[4,5] and anxiolytic in man.[6,7] Propranolol may directly depress by a local-anesthetic-like action at the membrane.[8] These effects imply that a reduction in anesthetic requirement might result from propranolol administration.

Accordingly, we investigated whether propranolol given acutely or chronically might modify the minimum alveolar concentration (MAC) of halothane. At the same time, we determined whether the beta-adrenergic stimulator, isoproterenol, affected halothane MAC.

Cessation of propranolol treatment has been reported to cause a hazardous increase in myocardial ischemia. The argument for discontinuing propranolol prior to anesthesia is that continued beta-adrenergic blockade may make the cardiovascular system more susceptible to the depressant effects of anesthesia[9-12] or the stress of surgery.[13] To determine whether propranolol alters the cardiovascular response to anesthesia, blood pressure (BP) and heart rate (HR) were measured before and after propranolol administration at equal anesthetic doses.

MATERIAL AND METHODS

Healthy, unpremedicated dogs of various ages, breeds, sex, and weight (19.6 kg ± SE 1, range 14 to 22 kg) were anesthetized with halothane-O_2. A cuffed endotracheal tube was introduced without the use of muscle relaxants, and breathing was controlled with a volume-limited respirator. Intermittent end-tidal gas samples were obtained from the end of the endotracheal tube via a nylon

catheter. Halothane was analyzed with a Beckman LB-1 infrared analyzer. Esophageal temperature was maintained at 37.5 ± 1° C by heating pads and ice. MAC was determined as described previously.[14] All measurements were made after at least 15 minutes of a constant end-tidal halothane concentration.

Arterial blood was drawn via catheter from the femoral artery for Pao_2, $Paco_2$, and pH. $Paco_2$ was maintained at 25 ± 2 torr (SEM), a level which does not influence MAC.[15] Blood pressure, from the femoral artery, and HR were recorded on a Grass polygraph.

Acute Experiments.—After induction with halothane, control MAC was determined in 8 dogs. Isoproterenol (0.8 μg/ml) was administered as a continuous IV infusion. MAC again was measured at an HR increased to 80% above control levels by adjustment of the isoproterenol infusion. Twelve ± 2 minutes after measurement of this "isoproterenol MAC," propranolol (2 mg/kg) was injected. To determine whether the propranolol had completely blocked beta-receptors, isoproterenol was infused for 5 minutes at the same speed as had previously doubled the HR, which now remained unchanged by the isoproterenol. After this confirmation, the propranolol MAC was determined. Finally, a large propranolol dose (10 mg/kg) was injected 106 ± 15 minutes after the 2 mg/kg propranolol injection. Following this, we again measured MAC.

Chronic Experiments.—Since propranolol commonly is administered chronically, we also examined whether chronic administration differed from acute administration in its effect on MAC. Halothane MAC was determined in 6 normal unmedicated dogs. Propranolol (200 mg) was then administered orally each day (mean 11.6 mg/kg/day: range 9.5 to 16.7 mg/kg/day) for about 10 days (range 8 to 11 days), after which halothane MAC was redetermined. Following the determination of this chronic propranolol MAC, we examined whether such chronic oral administration blocked HR response to the isoproterenol infusion (0.8 μg/kg) previously found to double HR. In both acute and chronic experiments, each MAC was corrected to a body temperature of 37° C.[16] Results were analyzed for statistical significance by paired analysis with Student's *t*-test. A p value of less than 0.05 was accepted as significant.

RESULTS

Acute Experiments.—Isoproterenol infusion initially decreased BP by 22% (table), but by 10 minutes after the start of infusion, pressure had returned to control values. The 2 mg/kg propranolol injection did not induce a fall in BP. HR transiently decreased 27%, but rapidly returned to control values (table). Isoproterenol infusion following propranolol did not increase pulse rate. With the larger dose of propranolol (10 mg/kg), BP initially decreased and HR increased (table), these values returning to or toward control levels in about 20 minutes (fig 1). MAC was not affected significantly by any treatment (fig 2, table).

Chronic Experiments.—After oral propranolol administration (200 mg/day) for 10 days, BP values at any given level of halothane anesthesia were nearly the same as prior to propranolol administration, and HR changed little (fig 3). Incomplete atrioventricular block was observed in 1 dog

TABLE

Mean Arterial Pressure and Heart Rate Changes After Isoproterenol or Propranolol

			Propranolol 2 mg/kg		Propranolol 10 mg/kg	
	Control (N = 8)	After 5 minutes of isoproterenol infusion (N = 8)	After 5 minutes (N = 7)	After 5 minutes of isoproterenol infusion (N = 6)	After 5 minutes (N = 5)	After 20 minutes (N = 5)

*Absolute % ± SEM. N = 8 for all except propranolol 10 mg/kg, where N = 6.

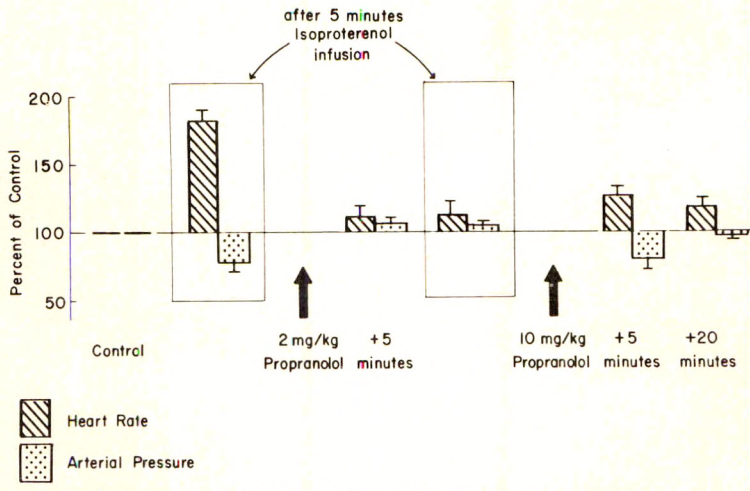

FIG 1. Heart rate and mean arterial pressure in acute experiments are given as a percent of values obtained during halothane anesthesia prior to isoproterenol or propranolol injection. Heart rate and pressure changes following propranolol on the average were small and transient. Before, but not after propranolol injection, isoproterenol increased heart rate and decreased blood pressure. For number of animals at each point see the table.

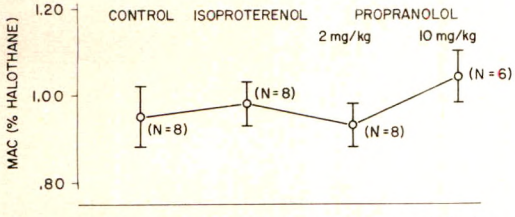

FIG 2. Neither an IV isoproterenol infusion sufficient to double the heart rate nor 2 or 10 mg/kg IV injection of propranolol altered MAC for halothane in acute experiments. MAC values are given as average percent halothane ± SEM.

given the largest dose of propranolol (16.7 mg/kg/day). Another dog showed incomplete beta-blockade, indicated by its response to isoproterenol. No significant changes in MAC were seen. Halothane MAC was 0.99 ± 0.08% before chronic propranolol administration and 1.08 ± 0.08% after.

DISCUSSION

Propranolol given either acutely or chronically did not make the average dog more susceptible to halothane-induced hypotension or bradycardia (figs 1 and 3). Thus, our data do not support the argument that propranolol must be discontinued before halothane anesthesia. However, such data may not be immediately extrapolated to patients, particularly those with heart disease conferring limited cardiovascular reserve.

Moreover, we did not explore the interaction of propranolol on myocardial contractility or cardiac output. It should be noted that the larger doses of propranolol given IV over a period of 3 to 4 minutes did cause a mild, transient hypotension and tachycardia during halothane anesthesia. Tachycardia at this time may have resulted

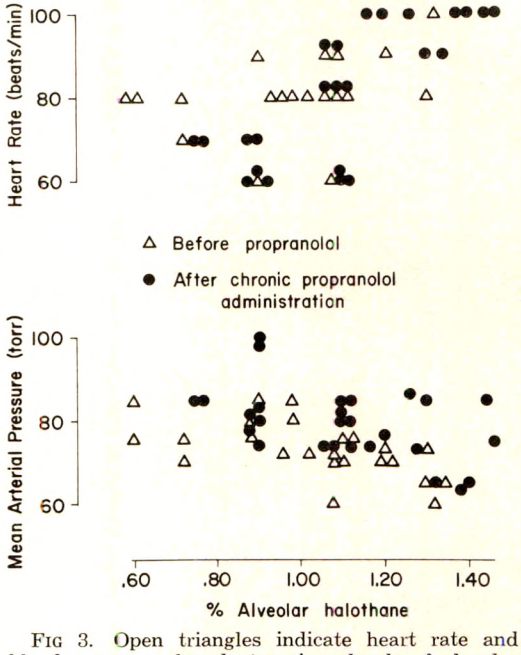

FIG 3. Open triangles indicate heart rate and blood pressures found at various levels of alveolar halothane in 6 unmedicated dogs. Closed circles indicate heart rate and pressure found after oral administration of 200 mg/day of propranolol for 10 days. It is apparent that propranolol did not significantly alter response of these variables to depressant effect of these levels of halothane.

from incomplete beta-sympathetic blockade in the presence of baroreceptor stimulation due to the hypotension. A possibility we believe unlikely is that reduced sympathetic activity may have caused tachycardia associated with transient acute cardiac dilatation.

Our findings that neither acute nor chronic administration of propranolol alters halothane MAC appear to conflict with reports of depression following propranolol administration.[4,5] They also appear to conflict with studies suggesting synergistic action between propranolol and other CNS depressants.[17,18] However, the doses of propranolol used in these other studies were 10 times larger than we used. In agreement with our work, Lader and Tyrer[19] found in normal human subjects that no central effects of propranolol were produced by 120-mg doses given acutely. They pointed out that the dosage in most experimental studies was much greater than used therapeutically. Also, since the longer the duration and higher the dosage of propranolol therapy, the higher the incidence of depression,[7] it is possible that our chronic experiments (10 days) were too short in duration to reveal the true depressant effect of propranolol.

Isoproterenol not having been reported to enter the CNS in significant quantities, it is hardly surprising that it did not affect MAC. In contrast, propranolol readily crosses the blood-brain barrier,[20] causes inhibition of the stimulatory effect of catecholamines on carbohydrate and lipid metabolism,[21-23] but does not alter brain noradrenaline after acute or chronic administration.[24] This uncertainty regarding the effect of propranolol on cerebral catecholamines prohibits any prediction of effect based on the known correlation between central amine reduction and MAC,[25] and indeed, although propranolol increases sleeping time in rats and mice following chloral-hydrate administration, this effect is not correlated with changes in brain amine concentrations.[24]

ACKNOWLEDGMENT

Halothane (Fluothane®) and propranolol (Inderal®) were contributed by Ayerst Laboratories.

STEROIDS AND HEPATITIS. Corticosteroids are the most widely used drug in severe viral hepatitis despite the lack of proven efficacy. In this study 29 patients with severe acute viral hepatitis were randomly assigned to a placebo or a methylprednisolone group for a 16 week treatment period. Both groups were comparable in clinical findings, laboratory results and presence of bridging necroses on liver biopsy. Seven of 14 patients receiving methylprednisolone (initially 48 mg gradually tapered to 12-32 mg during the last six weeks of treatment) and 2 of 15 receiving placebo died. Although these mortality differences were not statistically significant between groups a deleterious effect of steroids is suggested by the increased mortality in patients treated with methylprednisolone. Furthermore as many as 4 patients developed serious complications of steroid therapy during the study. In contrast, steroids are of proved efficacy in the treatment of chronic active hepatitis which is often associated with elevated immunoglobulins and autoimmune antibodies. The authors conclude that methylprednisolone did not improve the prognosis of severe acute viral hepatitis and may have produced a detrimental effect. *(Gregory PB, Knauer CM, Kempson RL et al: Steroid therapy in severe viral hepatitis. A double-blind, randomized trial of methylprednisolone versus placebo. NEJM 294:681-687, 1976)*

Circulatory Responses and Halothane Concentrations During Gastric or Gallbladder Traction With and Without Neuromuscular Blockade

ROBERT K. STOELTING, MD*
CHRISTINE PETERSON, RN†
JAMES A. MADURA, MD‡
Indianapolis, Indiana§

Systolic and diastolic blood pressures and heart rates did not change significantly and ventricular dysrhythmias did not occur during gastric or gallbladder traction in patients anesthetized with N_2O-halothane, with or without d-tubocurarine or pancuronium neuromuscular blockade.

Systolic and diastolic blood pressures and heart rates just before abdominal viscera traction were less ($p<0.05$) in patients paralyzed with d-tubocurarine than with pancuronium despite similar arterial halothane concentrations. In contrast, these measurements in patients without neuromuscular blockade were similar to those during pancuronium paralysis despite significantly greater arterial halothane concentrations in the unparalyzed patients.

The authors conclude that circulatory responses during gastric or gallbladder traction are clinically insignificant during N_2O-halothane administration, with or without d-tubocurarine or pancuronium neuromuscular blockade. Intraoperative blood pressures and heart rates were influenced by the neuromuscular blocker chosen. Neuromuscular blockade permitted anesthetic maintenance with lower arterial halothane concentrations than when paralysis was not present.

SUDDEN blood pressure decreases coincident with intra-abdominal operative manipulations may represent autonomic nervous system reflex responses.[1] Presumably, splanchnic sympathetic afferent fibers are stimulated and subsequent efferent activity produces splanchnic vasodilation with associated circulatory changes.[2] Burstein[1] described a celiac plexus reflex characterized by decreased systolic blood pressure, narrowed pulse pressure, and unchanged heart rate as most likely to occur during gallbladder or gastric operations. Circulatory responses with abdominal viscera manipulation during N_2O-halothane anesthesia have not been measured. Further, a speculated protective effect against autonomic nervous system reflexes by d-tubocurarine-produced autonomic ganglion blockade has not been documented.[3]

This report demonstrates that circulatory changes in response to gastric and/or gallbladder traction are minimal during N_2O-halothane anesthesia with or without d-tubocurarine (dTc) or pancuronium neuromuscular blockade. However, the neuromuscular blocker choice did influence the intraoperative blood pressures and heart rates, while

lower maintenance arterial halothane concentrations were present in paralyzed than in nonparalyzed patients.

METHODS

Twenty-seven chronically obese adults undergoing elective jejunoileal small bowel bypass operations were studied. All received morphine (6 to 10 mg) and scopolamine (0.4 to 0.6 mg) for preanesthetic medication. Anesthetic induction was with thiamylal (300 to 500 mg) and succinylcholine to facilitate endotracheal intubation. Ventilation was controlled with a volume ventilator adjusted to maintain $Paco_2$ near 30 torr. Anesthetic maintenance was with 60% N_2O-O_2 and halothane. Halothane was delivered from a Copper Kettle® vaporizer using systolic blood pressure as a guide for adjusting the vaporizer O_2 flow. Five minutes before the anticipated skin incision, 10 patients received 0.4 mg/kg of dTc and 10 patients received pancuronium (0.08 mg/kg). The remaining 7 patients received no neuromuscular blockers other than succinylcholine to facilitate intubation. Blood pressure was recorded continuously from an intra-arterial catheter placed in the radial artery. Heart rate and cardiac rhythm were determined from lead 2 of the ECG.

After the peritoneum was opened and before placement of any retractors, a control blood pressure and ECG were recorded and arterial blood was obtained for Pao_2, $Paco_2$, pH, and halothane concentration. Vaporizer O_2 flow and diluent gas flows had been unchanged for at least 10 minutes. Halothane concentrations were converted to equivalent MAC values, assuming a halothane blood-gas partition coefficient of 2.4 and a halothane MAC for this age group equal to 0.76 vol/100 ml.[4] Gastric traction was then applied for 30 seconds with blood pressure and ECG recorded continuously during and for 30 seconds after releasing the traction. When blood pressure and heart rate were again judged to be unchanging (3 to 5 minutes later) the same sequence was repeated with 30 seconds of gallbladder traction in only the paralyzed patients. Skeletal muscle relaxation was inadequate to permit gallbladder traction in the patients without neuromuscular blockade. Chronically obese patients undergoing similar operations were chosen to permit the same surgeon to provide the viscera traction in all patients.

Data were analyzed by Student's *t*-test and $p<0.05$ considered statistically significant. This study was approved by the Indiana University School of Medicine Clinical Research Committee.

RESULTS

All patient groups were similar with respect to age, weight, and preoperative blood pressure and heart rate (table 1). Control blood gases and pH were similar just before gastric traction, but arterial halothane concentrations were significantly less in the paralyzed patients. Control circulatory measurements (systolic and diastolic blood pressure and heart rate) during anesthesia and just before gastric traction were significantly less in patients paralyzed with dTc than in patients not paralyzed or those paralyzed with pancuronium (table 2).

Gastric traction did not significantly alter systolic and diastolic blood pressures or heart rates with or without competitive neuromuscular blockade (table 2). Likewise, gallbladder traction did not produce significant circulatory responses in paralyzed patients. No patient developed ventricular dysrhythmias.

The initial gastric traction was applied 39 ± 4 minutes (mean ± SE) after dTc administration and 40 ± 3 minutes following pancuronium. Twitch response to ulnar nerve stimulation (Peripheral Nerve Stimulator) was completely abolished in these patients. Ulnar nerve stimulation showed no evidence of neuromuscular blockade just before applying gastric traction in those patients receiving only succinylcholine for intubation.

DISCUSSION

Blood pressure and heart rate did not change significantly and ventricular dysrhythmias did not occur in response to gastric or gallbladder traction during N_2O-halothane anesthesia. Speculation that autonomic ganglion blockade from dTc might attenuate circulatory responses to intra-abdominal manipulation could not be confirmed, since significant changes did not occur with or without neuromuscular blockade.

Our findings are in contrast to those reported by Rocco and Vandam[5] describing arterial hypotension with or without bradycardia in 55/68 patients in response to manipulation of the abdominal viscera. However, these authors reported that circulatory changes occurred most often with stimulation of the parietal peritoneum, while gastric or gallbladder traction, as in our study,

frequently produced no circulatory changes. Nevertheless, Smith[6] reported 10 instances of celiac plexus reflex responses, occasionally accompanied by an unobtainable blood pressure, during gastric or gallbladder traction.

Anesthetic agents may influence autonomic nervous system reflex activity. For example, Briscoe and Millar[7] reported that cyclopropane, diethyl ether, and halothane impaired sympathetic ganglion transmission. However, the role anesthetic agents may

have exerted on circulatory responses to abdominal viscera manipulation in our study or in previous reports[5,6] cannot be determined.

Despite similar arterial halothane concentrations, control systolic and diastolic blood pressures and heart rates were significantly less in patients paralyzed with dTc than in patients paralyzed with pancuronium. In addition, a significantly greater maintenance arterial halothane concentration was necessary to prevent movement during operation in unparalyzed patients. For example, greater than 1 MAC (about 0.5 MAC N_2O plus 0.62 MAC halothane) was present in unparalyzed patients, while less than 1 MAC (from the combined effects of N_2O plus halothane) was present in paralyzed patients. Even with the higher halothane concentrations, the intraoperative blood pressures tended to be greater than awake values in unparalyzed patients.

It is tempting to speculate that surgical stimulation was responsible, but it must be remembered that stimulation was similar in patients paralyzed with dTc and at lower halothane concentrations. Further, blood pressure measurements during pancuronium paralysis were also near the awake levels, but the arterial halothane concentrations were significantly less than in unparalyzed patients, being near those concentrations present during dTc paralysis. We conclude that this is evidence that the choice of neuromuscular blocker, as previously suggested,[8] may influence cardiovascular status during operation. Further, neuromuscular blockade permits maintenance of anesthesia with lower arterial halothane concentrations than when paralysis is not present.

Whether similar circulatory differences between dTc and pancuronium would be present with smaller doses of these drugs or lesser degrees of neuromuscular blockade cannot be stated. All our patients were obese, and calculation of neuromuscular blocker dose on the basis of body weight (mg/kg) resulted in large single-dose administration of dTc (average 53 mg) or pancuronium (average 9.4 mg). This produced a neuromuscular blockade characterized by no visible twitch response to ulnar nerve stimulation about 40 minutes later when the anesthetic concentration and circulatory measurements were determined.

If lower blood pressure during dTc paralysis reflects autonomic ganglion blockade, it is conceivable that smaller dTc doses would have produced less ganglion blockade and subsequent blood pressure decrease. As pancuronium produces little autonomic ganglion blockade, this should not be a consideration with the doses used in this study.[9]

Laryngotracheal Residue During Endotracheal Anesthesia

CHONG M. LEE, MD*
JAMES E. GILDEA, MD†
Hershey, Pennsylvania‡

THAT liquid residue may accumulate in the space between the cuff of the endotracheal tube and the larynx during general anesthesia has long been recognized in practice. A question arises, however, as to the amount of this matter that may remain in the trachea before extubation at the end of a surgical procedure. The present study was conducted to investigate, by the process of laryngotracheal toilet, the amount of such matter found in various clinical situations.

MATERIALS AND METHODS

Subjects were 83 unselected patients undergoing anesthesia for elective surgery. All were between 17 and 25 years of age and in ASA physical status I, II, or III. Patients were divided into 3 groups according to the operative position in which they were placed. All patients received IM 0.5 mg of atropine sulfate in conjunction with a sedative or narcotic 1 hour before operation. Sodium thiopental and succinylcholine were used to facilitate induction and intubation. Anesthesia was maintained with either N_2O, Innovar®, and muscle relaxant or enflurane and N_2O, with or without muscle relaxant. Respiration was assisted or controlled throughout.

The specially designed endotracheal tube (figure) was tested in 20 patients. After the tip of the endotracheal tube was passed beyond the vocal cord under direct laryngoscopy and the fluted proximal cuff was inflated, the tube was advanced until the distal margin of the inflated fluted cuff sat on the larynx tightly. Then the distal cuff was inflated and the tube was secured. Finally, the fluted cuff was deflated completely and the inflating tube was clamped to prevent self-inflation of the fluted cuff.

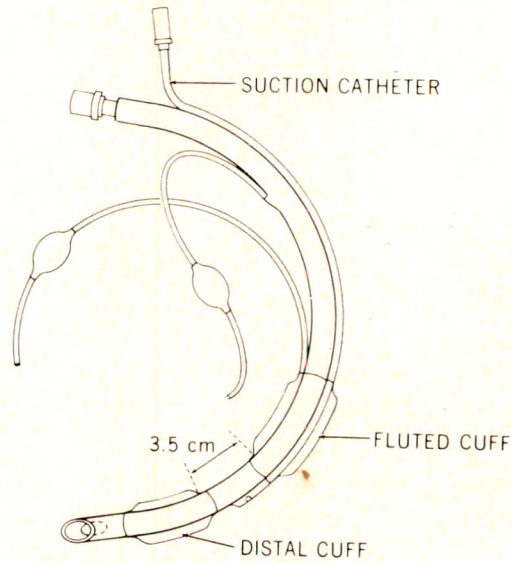

FIGURE. Combined 8 Portex endotracheal tube and suction catheter (12 French). Fluted cuff is inserted over endotracheal tube.

After the tube had been secured following intubation, an average of 2.4 ± 0.2 ml of normal saline solution was injected through the aspiration device on the endotracheal tube into the laryngotracheal space. The normal saline injected was aspirated immediately, and the volume recovered by this maneuver was measured. At the end of the

Average operation time: a - 152 ± 13 min
b - 125 ± 11 min
c - 183 ± 25 min

operation, the fluted proximal cuff was again inflated to obstruct the larynx from the oral cavity.

Laryngotracheal toilet was performed by means of suctioning the liquid matter into a Luken's tube and the volume measured. Student's t-test was used for statistical analysis of variance.

RESULTS

The specially designed endotracheal tube recovered 97.6% of the saline solution in the 20 patients tested with this device. No liquid residue was obtainable in 16 of the 32 patients in the Trendelenburg position, and less than 0.5 ml was recovered from each of the remainder of the patients in this group. The average volume (0.2 ± 0.0 ml) ($p<0.001$) in this group was significantly less than that of the supine group. An average of 1.3 ± 0.2 ml of laryngotracheal residue was aspirated from the supine patients. Those in sitting position had an average of 2.2 ± 0.3 ml, which was about 60% more than the supine group, a statistically significant difference ($p<0.02$) (table).

The additional variables studied showed that men patients (1.6 ± 0.2 ml) ($p<0.001$) demonstrated larger volumes than women (0.7 ± 0.1 ml). Neither duration of operation nor type of anesthetic showed statistically significant differences in volume.

DISCUSSION

The liquid matter found to accumulate in the space between the cuff of the endotracheal tube and the larynx during anesthesia with endotracheal tubes is probably a combination of laryngotracheal mucosa, saliva, regurgitated gastric contents, endotracheal tube lubricant, and blood from lacerated oropharyngeal mucosa. The differences in the amounts found in the 3 different positions studied may be primarily due to the gravity effect.

Metha[1] has suggested placement of the cuff just beyond the true vocal cord in order to eliminate this potential space in the trachea. He has also suggested tilting the operating table 10° head-down while suction is being applied through the endotracheal tube to perform laryngotracheal toilet.

Jamie[2] has also described a method of performing toilet: (1) To aspirate the liquid matter from the mouth and throat, close the expiratory valve of the anesthesia circuit, kink the cuff inflating tube, and remove the clamp. (2) Inflate the lungs by a hard squeeze on the reservoir bag; the cuff inflating tube is then released and the endotracheal tube is rapidly removed. The lungs deflate forcefully as the tube is removed and the liquid matter in the upper part of the trachea is expelled into the mouth.

Such an endotracheal tube with an airway aspiration device as described for the present study can be useful during routine endotracheal anesthesia for laryngotracheal toilet prior to extubation.

ACKNOWLEDGMENT

The authors thank Dr. Allen E. Yeakel for his help in the preparation of this manuscript.

Butorphanol and Morphine: A Double-Blind Comparison of Their Parenteral Analgesic Activity

M. TAVAKOLI, MD*
G. CORSSEN, MD†
F. S. CARUSO, PhD‡

The analgesic effects of butorphanol tartrate and morphine sulfate were compared in 127 patients judged to have moderate to severe pain following major operations. The study was double-blind, and the drugs were given IM at several dosage levels. Scores for pain intensity and relief, as well as pain-intensity difference, were determind at 30, 60 and 120 minutes after medication, then were analyzed by a parallel-line assay method in a modified computer program. The analysis indicated butorphanol tartrate to be 7 times as potent as morphine sulfate. Peak analgesic effects were obtained at 60 minutes with both drugs. Side effects were minimal in degree and incidence. Neither butorphanol nor morphine induced any changes in blood pressure, pulse rate, or respiratory rate. These data, along with those from studies elsewhere, suggest that butorphanol is a safe, potent, and effective analgesic agent, with probably a low potential for inducing drug dependence.

OVER the years, a major objective of analgesic research has been to obtain an agent which retains the desirable analgesic property of morphine, has limited or no liability for producing physical dependence and can be totally synthesized without dependence on a supply of opium. Synthetic analgesics have been potent but they have also been highly addictive.

When it was observed that nalorphine, a narcotic antagonist, was also an effective analgetic,[1] a series of benzomorphans with concomitant analgesic and narcotic antagonist properties were synthesized.[2,3,4] The theoretical consideration that a molecule with both analgesic and narcotic antagonist properties would have a reduced liability for drug dependence proved correct, but psychotomimetic effects, occurring at or near therapeutically effective analgesic doses, added another dimension to the problem. In addition, usable agents were relatively weak analgesics compared to morphine.[5]

Recently, Monkovic's group[6,7] reported the total synthesis of butorphanol which is levo-N-cyclobutylmethyl-3,14-βdihydroxymorphinan (fig 1). Studies with this compound in laboratory animals demonstrated analgesic potency greater than morphine sulfate, narcotic antagonist activity equivalent to nalorphine,[8,9] a potent antitussive effect,[10] and an indication that its physical dependence liability was of a low level.[9,11] Data from studies conducted at the Addiction Research Center in Lexington, Kentucky, indicate a low physical dependence liability for butorphanol in human subjects.[12]

After butorphanol's safety and acceptability had been determined in normal volunteers and analgesic efficacy had been demonstrated in an open pain study, a comparison of butorphanol tartrate and morphine sulfate with respect to analgesic potency and incidence of side effects was undertaken as a double-blind study in postoperative

patients suffering moderate to severe pain. The results of this study are reported here.

METHODS AND MATERIALS

With an informed consent obtained in all instances, 127 patients meeting the investigative criteria were admitted to the study program. The men and women in the series were all adults judged able to evaluate and communicate their pain sensations. Pregnant individuals were not included, nor were patients with current or prior renal, hepatic, or hematologic disorders or a history of tolerance or addiction to narcotic drugs. Most of the patients had undergone major surgical procedures, including hysterectomy, laparotomy, hernia repair and arthroplasty.

The five groups were reasonably well balanced with respect to age, sex, weight, and intensity of initial pain (table 1). In all groups except that receiving the lowest dose of butorphanol, the distribution of female to male participants was about 2 to 1. The intensity of initial pain was predominantly rated severe in all groups.

Preoperative medication consisted of atropine or a combination of atropine and pentobarbital. Postoperatively, the experimental treatment consisted of single IM doses of either butorphanol tartrate at 0.73 mg (0.5 mg base), 1.46 mg (1 mg base), or 2.92 mg (2 mg base), or morphine sulfate at 5 mg or 10 mg. The test drugs were provided in identical vials* which were numbered consecutively and assigned to the patients in the order of their entrance into the study.

*Prepared and randomized as to drug and dose by Bristol Laboratories, Syracuse, New York.

Test agents were evaluated postsurgically in the recovery room. When the patient was alert enough to complain of pain, the degree was graded as 1=slight, 2=moderate, or 3=severe. Patients complaining of moderate or severe pain were assigned a patient number and then given an IM injection of 1 ml of the contents of the vial with the corresponding number.

After medication, close surveillance of the patient was maintained for a period of 5 hours. At 0.5, 1 and 2 hours following medication, the degree of pain was recorded and the degree of relief evaluated (0=no relief, 1=slight, 2=moderate, 3=good, and 4=complete). The difference between group mean scores initially and at each point of evaluation provided an additional index to drug effectiveness and was designated the pain intensity difference (PID). Blood pressure, pulse rate, and respiratory rate were determined each time the pain was evaluated. During the 5-hour period, it was left to the discretion of the investigator whether additional pain medication would be given at the patient's request.

On completion of the study, all the information was tabulated, the medication was decoded, and the data were analyzed. Summed values examined included (1) pain scores, (2) pain relief scores, (3) pain intensity differences. These were analyzed by a modified computer program for the parallel-line assay method as described by Finney[13] and others.[14] Analysis included (1) variance, (2) linear dose-response regressions, and (3) an estimate of butorphanol tartrate potency in relation to that of morphine sulfate.

RESULTS

Nine patients received additional medication during the primary 2-hour observation period; for purposes of statistical analysis, these patients were assigned pain intensity and relief scores of 3 (severe) and 0 (none), respectively. Omitted from statistical analysis was one patient (No. 31), receiving 2.92 mg of butorphanol, who, because of sleepiness and difficulty in breathing, was given 0.2 mg of naloxone intravenously 20 minutes after the initial medication. Also excluded from the analysis were patients No. 38, 91 and 101, who did not receive medication because these test vials had either been broken or inadvertently discarded.

The mean values for blood pressure, pulse, and respiratory rate recorded during

the two-hour period following medication showed no statistically significant changes within or between any of the 5 treatment groups. The means and standard errors of the various scores related to pain are listed in table 2 and graphically presented in figures 2, 3 and 4.

The response obtained with the 0.73 mg dose of butorphanol tartrate was significantly less than the responses to the two higher doses, 1.46 and 2.92 mg, but the latter doses did not significantly differ from each other. Also, the low dose of morphine sulfate was significantly less effective than the high dose. Thus, the sensitivity of this method for determining analgesic activity and differentiating between doses was evident.

With respect to relative potency, there was no statistical difference between 0.73 mg butorphanol tartrate and 5 mg morphine sulfate, or between 1.46 or 2.92 mg butorphanol tartrate and 10 mg morphine sulfate.

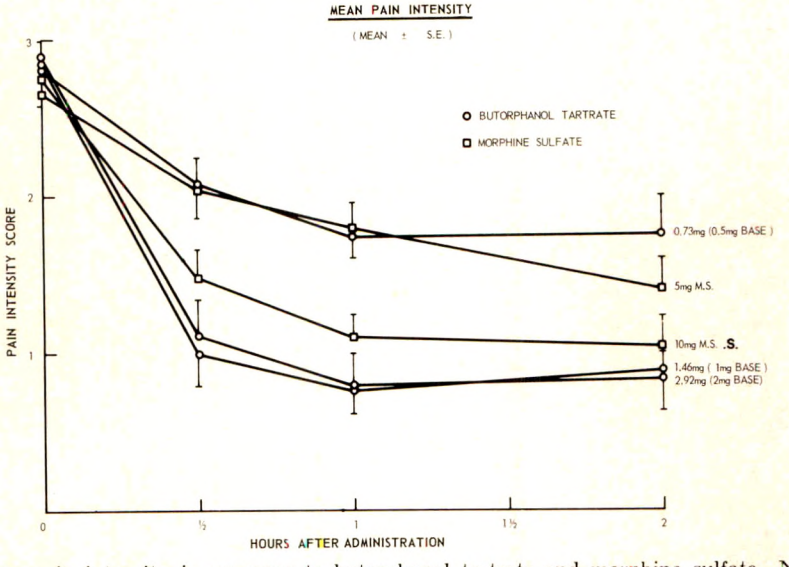

FIG 2. Mean pain intensity in response to butorphanol tartrate and morphine sulfate. Note that 0.73 mg butorphanol tartrate appears equivalent to 5 mg morphine sulfate and that 1.45 mg and 2.92 mg butorphanol tartrate appear slightly greater than 10 mg morphine sulfate. These data support the conclusion that butorphanol tartrate is 7 times as potent as morphine sulfate.

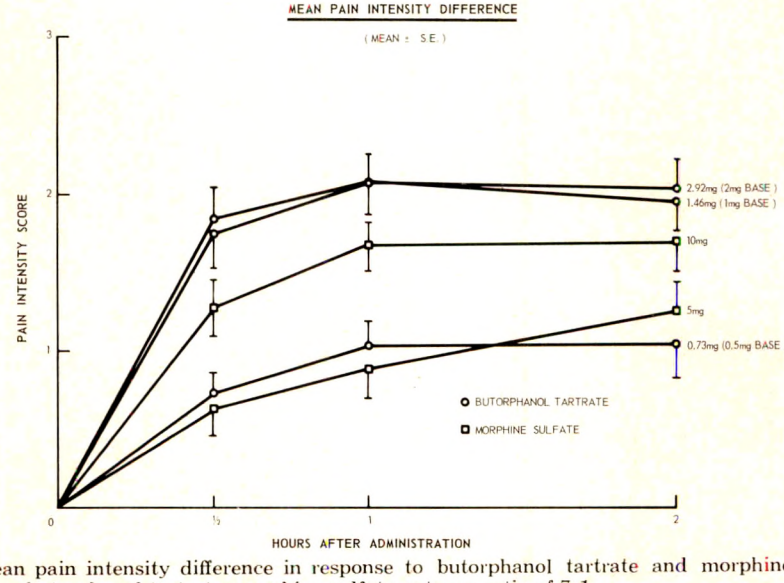

FIG 3. Mean pain intensity difference in response to butorphanol tartrate and morphine sulfate. The data indicate a butorphanol tartrate:morphine sulfate potency ratio of 7:1.

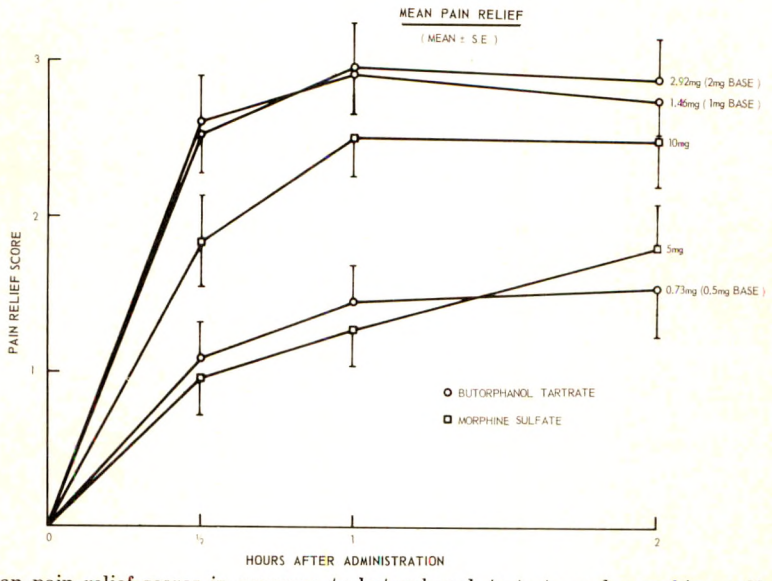

FIG 4. Mean pain relief scores in response to butorphanol tartrate and morphine sulfate. These data provide further support for a 7:1 butorphanol tartrate:morphine sulfate potency ratio.

When the parallel-line assay method was applied to the sums of pain intensity, pain-intensity difference, and pain relief, sufficient linearity and parallelism were obtained to validate the use of this method. The sum of pain intensity proved to be the most reliable for estimating relative milligram:milligram potency of the two agents. Calculations indicated that butorphanol tartrate was seven times as potent as morphine sulfate as an analgesic agent.

The incidence and type of side effects were not remarkable (table 3). With butorphanol, the predominant side effect was drowsiness; there were two instances of nausea. Results with morphine sulfate were similar. The number of side effects reported was so minimal that statistical evaluation was not warranted.

DISCUSSION

The clinical measurement of pain and its relief constitutes a difficult area of research. Attempts at measurement are strongly influenced and complicated by personal and environmental factors as well as by extenuating physical or psychological circumstances. These variables make it difficult to obtain a study population sufficiently homogeneous for a comparative analgesic bioassay. In the study described above, the test groups were relatively homogeneous as indicated by the vital statistics (table 1) and the definite responses to medication. Statistically significant differences in effectiveness were established between the low and high doses for each of the test drugs.

However, variability associated with biological response and with uncontrollable

TABLE 3
Summary of Incidence and Type of Side Effects Reported

	Side effect	½ hr	1 hr	2 hr
Butorphanol tartrate 0.73 mg (0.5 mg base)	Sleepy	1	—	—
Butorphanol tartrate 1.46 mg (1 mg base)	Drowsiness/sleepiness,	1	4	1
	nausea	—	—	1
Butorphanol tartrate 2.92 mg (2 mg base)	Drowsiness/sleepiness,	3	4	2
	nausea	—	—	1
Morphine sulfate 5 mg	Drowsiness/sleepiness,	—	2	2
	nausea	—	—	1
Morphine sulfate 10 mg	Nausea	1	1	1
	Nausea and vomiting	—	—	1

factors within a test population always influences biologic assays. The fact that the two larger doses of butorphanol tartrate did not differ significantly from each other does not necessarily indicate a ceiling effect, but is more likely a reflection of biologic variability and the close interval between doses. In a similar study by Dobkin,[15] the same low and mid doses of butorphanol did not differ statistically over the entire two-hour observation period, but they were effective analgesic doses and the effects were distinquishable at the half-hour interval. A more recent study by the same investigators demonstrated dose-related responses at 1 mg, 2 mg and 4 mg of butorphanol tartrate, with the largest dose affording almost complete relief of pain.[16]

Data from our study suggest that in providing relief from pain (table 2 and fig 2-4), the low doses of butorphanol and morphine were approximately equivalent, and that either the mid or the high dose of butorphanol was approximately equivalent to the high dose of morphine sulfate. Because of the variables noted above, the latter relationship is open to question.

Dobkin[15] reported this same magnitude of potency difference as we found (7:1) between butorphanol tartrate and morphine sulfate. Possibly, when the dose intervals with butorphanol tartrate and the size of the test population are expanded, 1.46 mg will approximate 10 mg morphine sulfate, and larger doses of butorphanol will exceed this in effectiveness.

Following IM administration, all doses of butorphanol tartrate achieved maximal effects within one hour (fig 2-4), and in each instance this maximal level was maintained to two hours, the last observation period for which a score was determined. With morphine sulfate, the effect of the 5 mg dose seemed more pronounced at the latter point than 0.73 mg of butorphanol tartrate. Although duration of effect was not an objective of this study, the data suggest that butorphanol effects probably last about as long as those of morphine sulfate.

At the doses used, neither butorphanol nor morphine induced any changes in vital signs or any significant side effects (table 3). Although respiratory depression is known to be associated with morphine, no such effect was observed with either butorphanol or morphine in our study.

Since the respiratory effect of morphine and butorphanol was not the subject of this study, no blood gas determinations or pulmonary volume measurements were made. Only the respiratory rate was counted. However, our impression to date is that butorphanol tartrate will prove to have only a limited depressant effect on respiration. More significant is the observation that the definitely analgesic doses of butorphanol in this study gave no evidence of causing mental aberration.

Currently available information thus indicates that butorphanol tartrate is a safe, potent, and effective analgesic agent with minimal undesirable side effects. If the expectation of minimal liability for producing physical dependence is fulfilled, this drug should find an important place among the analgesic agents now in use.

TRACHEAL TUBE POSITION. Movement of an endotracheal tube may occur with changes in head position. The authors investigated tube position in the trachea by radiographs taken in the semisitting position with the head flexed, extended or laterally rotated. Twenty adult patients intubated orally or nasally with an 8.0 mm endotracheal tube were studied. The tube moved a similar distance regardless of the route of intubation or status of cuff inflation. The distal end of the tube moved an average of 1.9 cm toward the carina with head flexion from a neutral position, 1.9 cm away from the carina with extension and 0.7 cm away with lateral head rotation. The carina was noted to move in the same direction as the tube thus minimizing the apparent tube to carina movement. These data suggest that inadverent extubation or endobronchial intubation could occur with the extremes of head movement from a neutral position. Head position should be considered when evaluating distal tube position in the trachea with chest radiographs. *(Conrardy PA, Goodman LR, Lainge F et al: Alteration of endotracheal tube position. Nitrous Oxide Encephalography: 5-Year Experience with 475 Pediatric Patients

RICHARD A. ELWYN, MD*
WALLACE H. RING, MD†
EDWARD LOESER, MD‡
GARTH G. MYERS, MD§
Salt Lake City, Utah‖

475 pediatric patients with a variety of neurologic conditions were subjected to encephalography, using N_2O as the contrast medium and N_2O-halothane as anesthetic agents. This technic is both safe and effective, as reflected by no mortality and satisfactory roentgenograms. By application of the principles of gas physics, postoperative discomfort has been greatly reduced, resulting in a more comfortable convalescence and earlier discharge.

A KNOWLEDGE of gas physics and pharmacokinetics is essential for safe anesthetic administration, and the dangers associated with the use of high concentrations of N_2O have received the attention of many authors. Saidman and Eger[1] warned that, during N_2O anesthesia, this gas may diffuse into entrapped air spaces and result in increased volume and/or pressure. They also suggested that use of N_2O as a contrast medium during pneumoencephalography (PEG) might prove advantageous to the patient, provided the same gas was used for general anesthesia. Munson[2] has warned that small air emboli may expand into larger bubbles during N_2O anesthesia.

By recognition of these characteristics of N_2O, we have attempted to provide patients undergoing gas PEG with a measure of operative safety, pain relief, and postoperative comfort not previously afforded with other modalities.

The technic described is unique in that a major reason for administering general anesthesia is not only to provide intraoperative pain relief, but to reduce postoperative discomfort.

METHOD

Observations were made on 538 pediatric patients subjected to PEG. Of these, the contrast medium was N_2O in 475 and air in 63. Patients with known increased intracranial pressure were examined by ventriculograms.

Infants up to 1 year of age received only atropine premedication, 0.02 mg/kg, just before the procedure. Older children received 2.2 to 4.4 mg/kg of hydroxyzine or 0.02 mg/kg of diazepam orally 4 hours preoperatively, followed by 2.2 to 6.6 mg/kg of pentobarbital or secobarbital 1 to 2 hours preoperatively and atropine. [We tended to omit the heavier premedication during the last 200 patients in the study, to have the children awake at the conclusion of the procedure.]

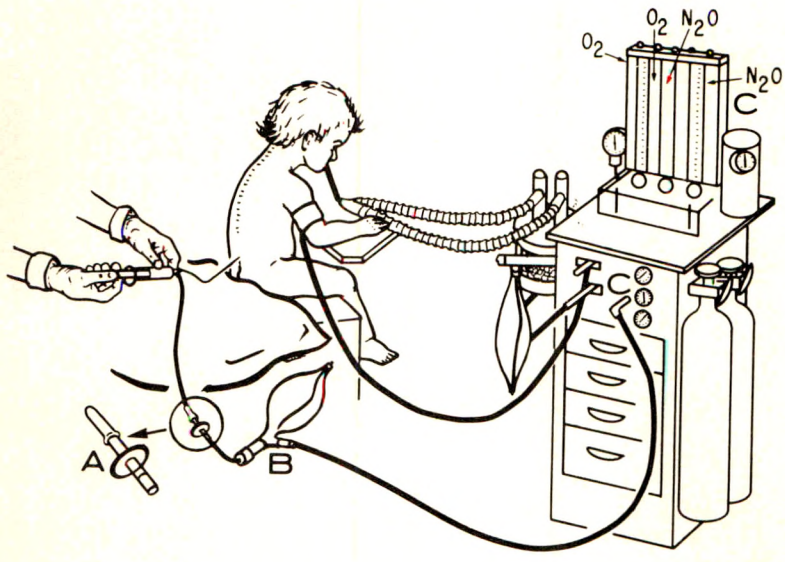

FIG 1. A. Sterile gas filter. B. Reservoir bag. C. Special N_2O flowmeter and outlet.

Anesthesia was induced with N_2O-O_2 (70:30) and 1% to 4% halothane in all patients and maintained by 0.25% to 1.0% halothane-N_2O-O_2 in N_2O-medium patients at the lightest level possible. In patients given air as the contrast medium, anesthesia was maintained with halothane and O_2, without N_2O. The vocal cords and trachea were sprayed with 4% lidocaine at a light level of anesthesia for endotracheal intubation. Respirations were controlled in most patients during the study period.

Blood pressure was monitored in all patients by the standard cuff technic and heart sounds by esophageal or precordial stethoscope. The legs were wrapped with elastic bandages prior to placement of the child in the sitting position.

Lumbar puncture and intrathecal gas instillation followed the usual sterile precautions. Opening pressures were determined at the level of the inion in the sitting position, usually 15 to 20 minutes after induction of anesthesia. The N_2O from a specially modified anesthesia machine (fig 1) was delivered into a reservoir bag, through a gas filter and into a sterile syringe. The cerebrospinal fluid (CSF) pressure was checked before withdrawal of the lumbar puncture needle, after the radiologist estimated that roentgenograms showed sufficient ventricular gas, and the total amount of gas injected and CSF removed was recorded. Patients were then placed supine and wrapped in a warming mattress maintained at 38° C. Nine radiographic films were taken by the usual PEG methods and body positions. In N_2O contrast medium patients the anesthetic administration was continued with 65% to 75% N_2O and halothane, until the attending physician determined that the roentgenograms were satisfactory. On completion of the examination, and after return to spontaneous ventilation, patients were extubated and taken to the recovery room. O_2 was given by face mask for the following hour.

Roentgenograms for gas persistence in the ventricles were taken on 10 randomly selected cases at 15 minutes, 1 hour, and 4 hours after anesthesia in N_2O-contrast patients.

Assessable patients 6 years old and over were evaluated for the presence and severity of headaches over a 5-day post-PEG period. Since the evaluation of headache is largely subjective by the observer as well as the patient, it was felt important that the study not influence the observer. All observations noted on the chart by the nurses were their own comments, as were their evaluations of the presence and severity of headaches. A headache was recorded as severe if the patient was essentially incapacitated, moderate if the child preferred to remain in bed except for toilet privileges, and mild if the child was up and about but complained of headache. Assessable patients were those

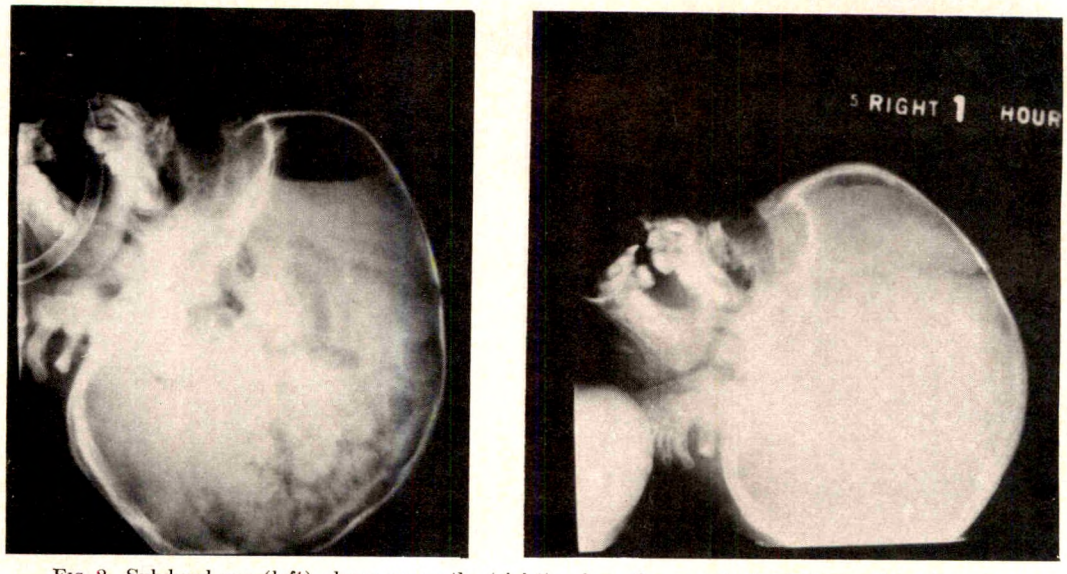

FIG 2. Subdural gas (left) clears promptly (right) when the anesthetic N_2O is discontinued.

not going to surgery or for other tests requiring sedation or anesthesia within the study period.

As hospital discharge is a definite endpoint, an analysis of the time from the PEG to hospital release was made in patients receiving no further procedures or tests. Anesthetic records and hospital charts were reviewed for neurologic and anesthetic complications. Emesis was tabulated from nursing notes.

RESULTS

The table summarizes headache incidence and duration in patients 6 years of age and older. There were no incapacitating or severe headaches in patients where N_2O was the contrast medium, while 44% of air-contrast patients had a severe headache at 1 day. The severe headaches with air-contrast studies lasted up to 4 days in 1 patient, but were usually decreasing at 2 days.

Although nearly half of the 437 patients vomited within the immediate postanesthetic period, all but 3% of the N_2O-contrast patients were no longer vomiting at 24 hours, and no N_2O-contrast patients vomited at 48 or 72 hours, while 5% of air patients still vomited at 72 hours.

Of 274 patients whose records were analyzed for time of hospital discharge, all the N_2O-contrast patients (n=255) went home by 96 hours while only 74% of 19 air-contrast patients were so fortunate. At 144 hours, 5% of the air-contrast group were still in the hospital.

Of the total 475 patients given N_2O, radiologic results were considered satisfactory by the pediatric roentgenologist in 93%, compared with 81% satisfactory results in the 63 air-contrast patients. In the N_2O group, 6.8% of the films were technically unsatisfactory, while 17.4% in the air-contrast group were so classified. An examination was listed as technically unsatisfactory if spinal tap did not produce CSF, the contrast gas did not reach the cerebral ventricles in quantity sufficient for good films, or excessive contrast gas in the subdural space obscured other structures. The only N_2O-contrast PEG with poor films resulted from operative depletion of an N_2O cylinder and subsequent loss of ventricular N_2O. Nitrous oxide injection ranged from 2-4 times the amount of CSF removed. The usual duration of anesthesia was 1½ hours.

48	9	0	22	39
72	1	0	33	11
96	0	0	16	6
120	0	0	11	0

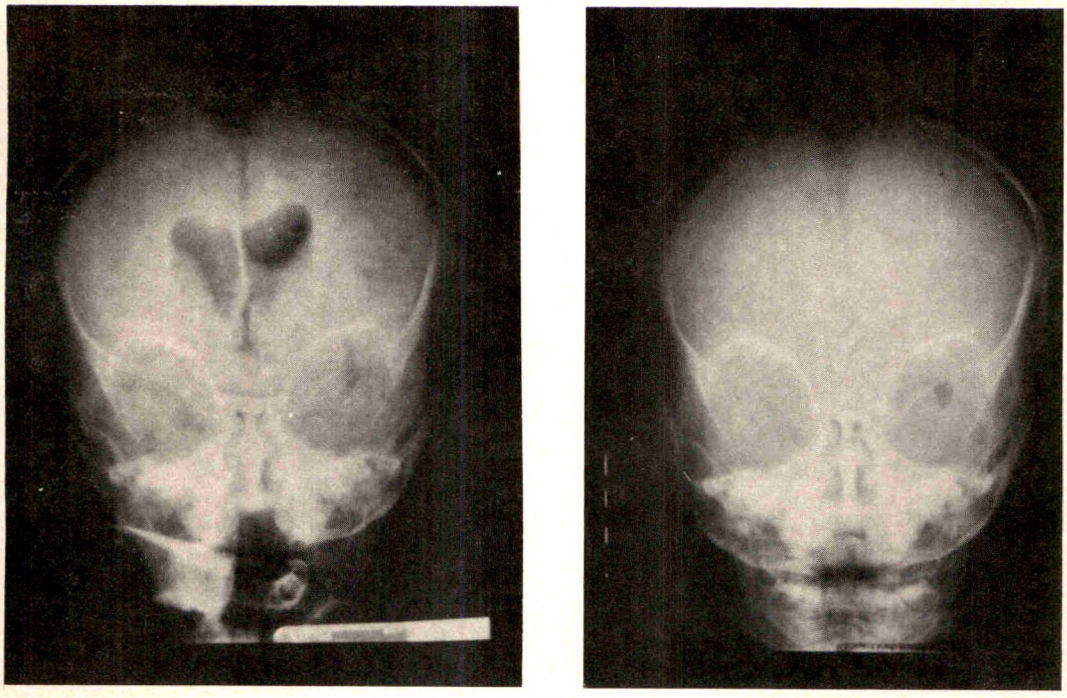

FIG 3. In the majority of cases x-rayed N_2O in the ventricles was almost completely gone by 15 min. postexamination.

X-rays on 10 patients taken for persistence of ventricular contrast gas revealed that only minimal gas remained at 15 minutes after cessation of the N_2O anesthetic (fig 3). Our N_2O medium infants showed minimal postoperative symptomatology but a temperature spike at 4 to 8 hours was not uncommon.

There were no fatalities in our series of 538 examinations and no neurologic complications. Operative complications included: (1) 6 cases of marked bradycardia, one of which resulted in a severe but rapidly reversible hypotension; (2) 3 patients (including the preceding) with severe hypotension, which occurred when the patient was placed in the sitting from the supine position; (3) 2 cardiac arrests, one following an inadvertent extubation and one in whom the exact cause was not identified but felt due to excessive anesthetic concentrations. (Both patients were resuscitated and recovered uneventfully.); (4) 8 extubations with reintubation accomplished without incident (except in [3] above).

Postoperatively, 18 patients developed croup.

DISCUSSION

The technic of using a gas to visualize the ventricular system has been used for over 57 years. The instillation of 20 ml of air causes an acute reaction in the awake patient; headache, pallor, sweating, bradycardia, hypotension, nausea and vomiting occur with varying severity. The examination requires pain obtundation, and the resulting depression can easily result in airway obstruction and hypoxia. In adults, local or sedation is usually satisfactory. Children, because of their temperment, require heavy sedation or general anesthesia. Well-managed general endotracheal anesthesia will eliminate airway obstruction and is recommended by textbooks of pediatric anesthesia.[3,4] In addition, while ketamine or neuroleptanesthesia may be effective operatively, they do not concern themselves with the *postoperative* morbidity. Our technique, with administration of general anesthesia, not only provides intraoperative pain relief but also reduces postoperative discomfort.

After the completion of air encephalography, most patients experience headache and nausea for a day or more, and air may remain in the ventricles for a week or longer. A temporary sterile meningitis develops, with a fever spike at 4 to 8 hours and an increase in protein and cell count lasting 2 to 3 days.

To find a better contrast gas medium than air, Aird[5] injected N_2O for dog encephalograms under local anesthesia, demonstrating its safety and showing total absorption within 1 hour. Newman,[6] also using local anesthesia, injected N_2O in humans undergoing encephalography but the N_2O diffused too rapidly from the ventricles for satisfactory roentgenograms. Since both Aird and Newman found cerebrospinal reactions with N_2O to be similar to those with air, we did not do routine postencephalogram lumbar punctures to establish the safety of N_2O by the lumbar route. We did, however, add the use of a bacterial filter to assure sterility in the examination.

We have carried Newman's study a step further by using N_2O for both general anesthesia and as the contrast medium. Since 100% N_2O is injected as the contrast gas and since only 65% to75% N_2O is administered in the anesthetic mixture, a pressure decrease would be expected after the injection because of the slightly greater partial pressure of N_2O in the ventricles than in the blood and brain. We found it necessary to inject 2 to 4 times as much N_2O as the contrast gas as would have been used with air as the contrast gas. In no case did the closing pressure reach a higher level than the opening pressure. As long as N_2O was continued in the anesthetic mixture in 65% or greater concentrations, sufficient gas remained in the ventricular system for satisfactory roentgenograms.

Smith and Crothers,[7] reviewing 80 PEG procedures in children <2 years of age, found subdural gas in 70%. Many of these infants had stormy postinjection courses, relieved promptly by puncture of the subdural space and gas withdrawal. With N_2O as the contrast gas, subdural gas may occur (fig 2, left) with the same frequency, but it is rapidly removed when the anesthetic N_2O is discontinued (fig 2, right). The result will be decreased CSF pressure within 15 minutes. The few postoperative symptoms reported in Results were presumably due to the irritative effects of N_2O and were related to the time of contact of the N_2O with the ventricular walls.

In the majority of cases, only minimal gas was seen on roentgenograms taken 15 minutes after N_2O cessation (fig 3). This small amount of gas remaining in the ventricles most likely represented inward diffusion of air or O_2 as the N_2O diffused out. The mask O_2 given patients should cause the more soluble O_2 to diffuse in first and later be replaced by N_2, each replacement lowering the amount of residual gas. Davidoff and Dyke[8] found that the duration of symptoms in days after gas PEG was in direct proportion to the amount of gas injected, relative to ventricular size. Schwab and von Storch[9] found that the severity of CSF cellular reaction varied directly with the volume of air used, and that the patients' symptoms were quantitatively related to the degree of cellular reaction. Davidoff[8] also recognized that the aim of the treatment in reducing morbidity from gas PEG should be to eliminate the gas as fast as possible after the examination. The rapid elimination of N_2O medium from the ventricles was most likely responsible for our decreased duration of postinjection symptomatology. Thus we agree with Davidoff that the duration of contact of the contrast gas with the ventricular system is responsible for most morbidity.

Davidoff, using air contrast in 94 patients, found 26% moderate or severe headaches at 48 hours and 5% remaining at 120 hours. Vomiting occurred in 8% of his patients at 48 hours, 7% at 72 hours, and 3% at 120 hours. We have listed his morbidity because of our paucity of air-contrast studies and to point out why hospital discharge time was shorter in our N_2O-contrast patients. Our N_2O medium patients were comfortable sooner despite the large volumes injected, up to 275 ml.

Mortality associated with gas encephalography has been reported as 0.2[8] to 8.2%.[10] Air embolism and brain herniation comprise the main reasons for death. Some of the unreported causes of death may have been from increased CSF pressure that can occur with N_2O anesthesia for air encephalography. Gordon and Greitz[11] state that "a combination of halothane and hypercarbia certainly has a far more significant intracranial pressure-elevating effect than nitrous oxide during pneumoencephalography."

In our series, the initial CSF pressure, taken 15 to 20 minutes after the induction of halothane-N_2O-O_2 anesthesia, was rarely elevated unless the patient's disease suggested the possibility of increased intracranial pressure. Our patients were carried on light anesthesia and kept hyperventilated. The closing pressures were never elevated within a few minutes after the injection of large volumes of N_2O contrast medium.

Jacoby and associates[12] consider air embolism as more likely to occur in children because a specified amount of gas will fill a larger portion of the ventricular system, and because needle placement is more difficult. During PEG fatal venous gas embolism has occurred with helium,[12] with air,[13] and with O_2.[14] Burko and Klatte[15] showed that dogs can withstand up to 5 times as much N_2O as air injected IV before succumbing. Paul[16] hypothesizes that a venous N_2O embolus with N_2O anesthesia would tend to be held in the gas phase and be "insoluble" because of the high N_2O partial pressure in venous blood. By ventilation with 100% O_2, however, nitrous oxide will be rapidly eliminated from the lung and then the venous blood, if cardiovascular integrity is present. The N_2O embolus rapidly decreases in size and becomes inocuous. Delayed gas embolism will not occur with N_2O because of the rapid loss of ventricular N_2O.

We experienced a venous N_2O embolus in a 2-week-old hydrocephalic infant undergoing ventriculography with N_2O contrast gas under N_2O-O_2 halothane anesthesia. After completion of a large ventricular injection, gas was noted in all the superficial scalp veins and a bradycardia began along with the characteristic murmur of air embolism. The patient was ventilated with 100% O_2, the murmur disappeared in 1½ minutes, and she recovered uneventfully.

Subdural hematoma and cardiovascular collapse[17] are suggested as possible neurologic complications of the rapid loss of CSF pressure when ventricular N_2O is eliminated. We had no patients in our series who exhibited either complication. Since we injected 2-4 times the amount of N_2O compared to CSF removed, our patients were faced with a less rapid decompression.

While most anesthetic administrations were uneventful some complications did occur. Extubation of the airway is a particular hazard in the mobile patient, and may occur in spite of adequate precautions. Short endotracheal tubes, failure of communication between anesthesia and radiologic personnel before required patient movement, spontaneous patient movement during the exam, and failure to adequately secure the endotracheal tube are all causes of extubation. Second-to-second monitoring of vital signs and close observation of the patient resulted in immediate recognition and reintubation. Severe bradycardia results from insufficient atropinization, too rapid contrast gas injection with sudden increased CSF pressure, and excessive anesthetic concentrations. If not recognized the bradycardia may result in severe hypotension and cardiac arrest. Our hypotensive episodes were transient and responded to positional change or reduction of the halothane concentration. No patients with postintubation croup were reintubated or tracheotomized and all responded to mist, steroids and IPPB with racemic epinephrine.

There were no fatalities in our series. It is likely the infant with the N_2O embolism would have succumbed if air had been used. Light halothane-N_2O-O_2 anesthesia has proven safe and effective when combined with N_2O encephalography. Strict attention to the details of anesthetic administration and airway management are necessary. So far as we know this is the first time the application of gas physics has been used to provide patients with postoperative pain relief.

PNEUMOPERITONEUM. Three adult patients developing free abdominal air and signs of a perforated viscus during positive pressure ventilation are described. Two received PEEP ranging between 10 and 15 cm water. Tidal volumes were about 1200 ml and peak inspiratory pressures were 50 to 61 cm of water. Fever and leukocytosis were present in all three patients. Two patients underwent negative exploratory laparotomies. It is speculated that air under positive pressure may enter perivascular lung tissue and find its way into the retroperitoneal space where subsequent rupture results in free abdominal air. Pneumoperitoneum secondary to air leak should be considered in patients receiving positive pressure ventilation and developing signs of perforated abdominal viscus. *(Stringfield JT, Graham JP, Watts CM et al: Pneumoperitoneum. A complication of mechanical ventilation. JAMA 235:744-746, 1976)*

The Effect of General Anesthetic Agents, Ouabain, and Aldosterone on Striated Muscle Contraction in Toad

L. AMARANATH, MD*
NIKAAN B. ANDERSEN, MD†
Cleveland, Ohio‡

Na^+ and K^+ transport, resting potentials, action potentials, and muscle contraction are interrelated in the excitation-contraction coupling process. Since anesthetics affect the electrogenic Na^+ transport mechanism in the toad bladder model and the coupled Na^+, K^+ transport in muscle, the authors tested the hypothesis that the effects of inhalation anesthetics on ion transport and muscle contraction are parallel. In this study, the effects were assessed of 4 inhalation anesthetics and, for comparison, the effects of ouabain and aldosterone, on contractions of toad sartorius muscle.

Cyclopropane, N_2O, ether, and halothane, as well as ouabain and aldosterone, increased twitch height in low concentrations. Halothane, ether, and ouabain decreased twitch height in high concentrations. The effect of cyclopropane and N_2O, ouabain, and aldosterone on muscle contraction closely paralleled their action on electrogenic Na^+ transport. This observation supports the hypothesis that the influence of these agents on muscle contraction is linked to the effect on active ion transport or that both effects are equally sensitive to anesthetic agents.

GENERAL anesthetics have been shown to stimulate or to inhibit active electrogenic Na^+ transport in toad bladder in concentrations used for clinical anesthesia.[1] Stimulation and inhibition have also been noted in the effect of anesthetics on the resting membrane potential and on the contraction of muscle. Cyclopropane, which stimulates Na^+ transport,[2] was found to increase the resting membrane potential[3] and enhance contractile force in striated muscle,[4] while halothane, which inhibits Na^+ transport, lowered the membrane potential[3] and decreased contractile force.[5,6]

Since Na^+, K^+ transport, resting membrane potentials, action potentials, and muscle contraction are related in excitation-contraction coupling,[7] we assumed that anesthetics have similar effects on active Na^+ transport in bladder and muscle[8] and hypothesized that the effects of inhalation anesthetics on muscle contraction and ion transport are linked. We, therefore, compared the effect of a series of anesthetic agents on contractions of toad sartorius muscle with effects on Na^+ transport in toad bladder.

The proposed hypothesis further suggests that nonanesthetics with strong effects on active Na^+ transport should also affect muscle contraction. Accordingly, we studied the effect of ouabain and aldosterone on toad sartorius muscle contraction and compared it with their well-known effects on Na^+ transport in toad bladder.[9,10]

METHOD

Toads, *Bufo marinus*, were pithed and muscle strips were isolated from the sartorius muscle. The strips, 1.5 cm long and 0.1 to 0.2 cm thick, were suspended at room temperature from a minimal-displacement pressure transducer in a sintered glass funnel that contained 60 ml of a toad salt solution:[11] NaCl 112 mM, KCl 1.9 mM, $CaCl_2$ 1 mM, $NaHCO_3$ 2.3 mM, and NaH_2PO_4 0.08 mM. The pH of 7.8 did not change during the experiment. The solution was aerated with O_2 and the chamber was continuously perfused with a fresh solution at a rate of 6 ml/min. The concentrations of the drugs to be tested were determined in pilot experiments, where we selected 3 concentrations of each compound that were multiples of each other, produced stimulation and, if possible, inhibition.

The muscle strips were electrically stimulated directly 5 times/minute with a supramaximal, 50 μsec impulse. The twitch was recorded and after stabilization the following agents were tested: cyclopropane 10, 40, and 80 vol %; diethyl ether 0.3, 0.6, and 1.2 vol %; N_2O 20, 40, and 80 vol %; halothane 0.3, 0.6, and 1.2 vol %; ouabain 10^{-12}, 10^{-9}, and 10^{-6} M; and aldosterone 10^{-7}, 10^{-6}, and 10^{-5} M. The anesthetics were delivered in O_2 from an anesthesia machine and the concentrations were assessed by gas chromatography. The solids were dissolved in toad Ringer's solution and added to the bathing solution by pipet. At the conclusion of the experiments, up to 3.5 μg/ml d-tubocurarine chloride was added to test the effect of neuromuscular blockade.

The drugs were added in increments and the concentration was increased when the resulting change in twitch response had been stable for 10 minutes. Each drug was tested 6 times in different muscle strips and the effect of each concentration was expressed as percent of control twitch height. Each experiment lasted about 2 hours. In the pilot experiments, we had ascertained that the twitch response in stabilized untreated strips did not change significantly during this period. Upon discontinuation of the inhalational anesthetics, twitch height returned toward control values.

The results were expressed as mean ± 1 SE and the significance of differences was assessed by Student's 2-tailed, unpaired *t*-tests.

RESULTS

Ether 0.3 and halothane 0.3 and 0.6 vol % increased twitch height ($p<0.01$) (table 1). With 1.2 vol %, both agents decreased twitch ($p<0.01$). Cyclopropane 10 and 40

	10^{-5}	$+16 \pm 2.0$	$p < 0.01$

*Results are means expressed as percent change from control twitch height of 6 experiments ± 1 SE.

†Significance of the differences between the treated and control muscles as assessed by Student's 2-tailed, unpaired t-test.

vol % gave stimulation ($p<0.05$ and 0.01), while 80 vol % had a variable effect. N_2O 20 vol % had no effect, but 40 and 80 vol % gave dose-dependent stimulation ($p<0.01$).

Ouabain, 10^{-12} M had no effect, 10^{-9} M increased twitch height ($p<0.05$) and 10^{-6} produced inhibition ($p<0.01$) (table 2). Aldosterone 10^{-7}, 10^{-6}, and 10^{-5} M increasingly enhanced twitch height.

The presence of curare 3.5 μg/ml in no instance affected muscle response.

DISCUSSION

In this study we accepted changes in the recorded twitch height as a direct expression for changes in contractile force. According to the Hill model for muscle,[12] we assume that we saw changes in contractility of the contractile element, rather than the elastic elements, in toad striated muscle strips. Neuromuscular continuity did not influence the results, because the muscles were stimulated directly. Furthermore, curare failed to alter twitch response with or without anesthetics.

In accordance with other authors,[6] we found that anesthetics depress or stimulate muscle contraction, depending upon agent and concentration. Pollard and Millar[6] reported that ether in concentrations of about 2 vol % depressed directly-evoked twitches in rat diaphragm, that halothane gave transient stimulation in concentrations of up to 5 vol %, and that cyclopropane up to 75 vol % stimulated the muscle. In our experiments, the 4 anesthetics tested produced sustained stimulation below a certain concentration while high concentrations of ether and halothane produced inhibition. Presumably cyclopropane and N_2O would also have decreased twitch height had we been able to further increase the concentration of these agents and still supply an O_2 tension of 150 torr.

Data by Price and coworkers[13] suggest that halothane decreases frog sartorius muscle heat production at 0° C. However, Strobel[14] has confirmed our observation regarding halothane potentiation of twitch height in frog sartorius at 25° C. We, therefore, propose that anesthetics in low concentration stimulate muscle contraction and inhibit contraction at higher concentrations. Anesthetic dosage affecting twitch height bears no relationship to minimal anesthetic requirements in the toad.[15] Cyclopropane stimulated contraction well above minimal anesthetic requirements (9 vol %), while ether depressed contraction at an equally effective anesthetic concentration (1.6 vol %). Thus, we assume that the anesthetizing effect of these anesthetics is not related to their effect on contraction. The nonanesthetic agents, ouabain and aldosterone, also increase muscle contraction.

*Means of 5 experiments ± SE. The results for ouabain and aldosterone are presented without statistical evaluation since they are calculated approximations from the literature.[9,10]

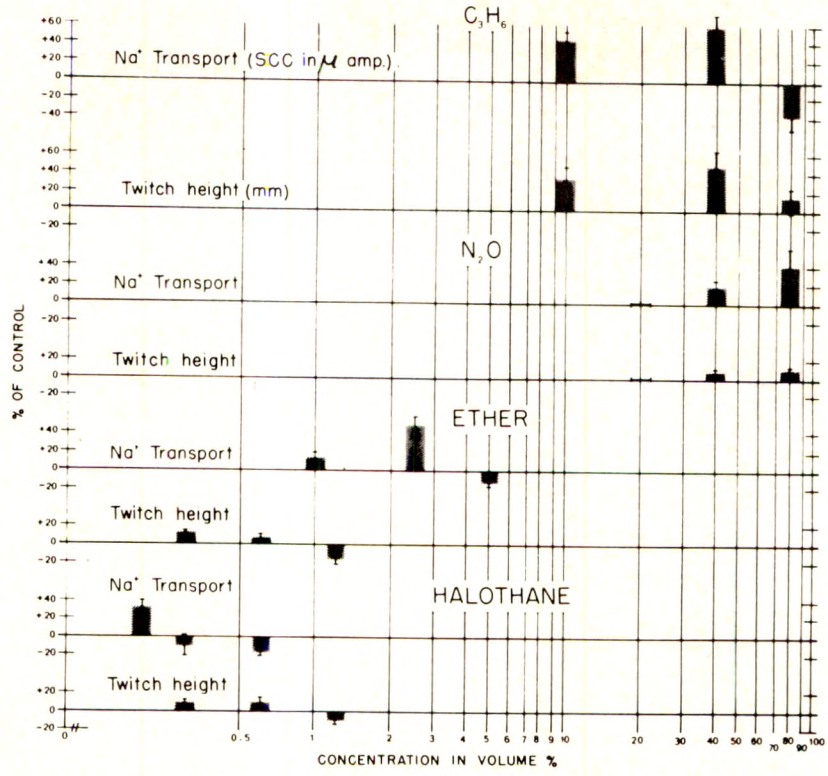

FIG 1. Effects of inhalation anesthetics on Na^+ transport[15] in toad urinary bladder and on twitch height in toad sartorius muscle. Vertical lines represent ± SE.

The relationship between the dose of the anesthetic and the electrogenic Na^+ transport has been studied previously.[1,2] Data from these studies and others involving ouabain and aldosterone are shown in table 3 and depicted, together with the present findings, in figures 1 and 2.

As can be seen, Na^+ transport in the toad bladder preparation was generally stimulated by low and depressed by high doses of all agents tested. The mechanical effects on striated toad muscle follow the same pattern of stimulation and then depression, but the two cannot readily be superimposed.

Aldosterone and ouabain are reported to stimulate and then inhibit Na^+ transport through mechanisms differing from those that apply for anesthetics. Ouabain presumably exerts its action through a direct effect on Na^+, K^+ ATPase,[9] aldosterone seems to stimulate metabolism,[10] and inhalational anesthetics probably depress transport through decreased permeability and stimulate transport through interaction with catecholamines.[2]

It may be a surprising coincidence that the anesthetic effects on muscle contraction in the toad are so closely paralleled by the anesthetic effects on the electrogenic Na^+ transport in the bladder, and that the effect of ouabain appears to run parallel to those of the anesthetics. The mechanism by which cardiac glycosides exert their positive inotropic effect is not fully elucidated. Investigators who focus on the glycoside effects on cation transport have postulated a

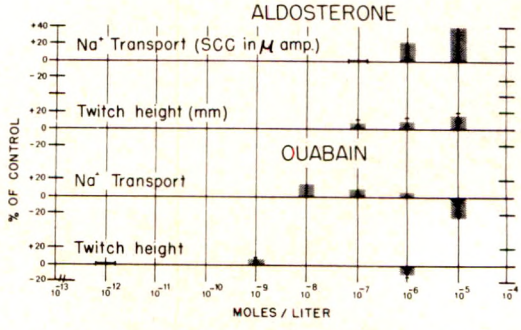

FIG 2. Effects of aldosterone[10] and ouabain[9] on Na^+ transport in toad urinary bladder and on twitch height in toad sartorius muscle. Vertical lines represent ± SE.

decreased Na^+ transport or increased Na^+ transport as possible explanations of the glycoside effect on contractility.[16]

Price[17] showed that "clinical concentrations" of halothane depressed myocardial contractility through an effect external to the contractile elements, possibly located in the cell membrane, with an effect on Ca^{++} availability to the contractile elements during the action potential. Our studies do not permit us to identify the mechanism by which Na^+ transport or twitch height was affected by the anesthetics and the nonanesthetic agents tested. The weight of the observations, however, suggests a membrane phenomenon as the common site of action.

The general "carrier" model for the metabolically mediated Na^+, K^+ membrane transport phenomena appears to be shared by toad bladder, muscle, and other cell membranes.[18] The effect of anesthetics on resting membrane potentials described by Kendig and Bunker[3] may be another expression of the relationship between anesthetic effects on Na^+, K^+ transport and muscle contractions. The effects on the membrane potential, of course, may be explained as hyper- or hypopolarization resulting from increased or decreased active Na^+, K^+ transport which, everything else being unchanged, would lead to changes in intracellular K^+ concentrations and the electrochemical K^+ gradient across the membrane, which is accepted as the main factor in the resting potential.[19]

Hodgkin and Huxley[20] demonstrated that the amount of Na^+ electrogenesis (Na^+ permeability during depolarization) depends on the resting membrane potential. If the resting potential is high, Na^+ electrogenesis will also be high and the activating system will be fully available.[21] Thus, anesthetics may increase twitch height by increasing the resting membrane potential and by making membrane depolarization more effective in activating the release of Ca^{++} to the contractile elements.

Our observations establish that anesthetics share effects on muscle contraction and ion transport with certain unrelated nonanesthetic agents. More work is needed to determine whether the active cationic transport phenomena in nonexcitable membranes resemble those in excitable membranes in their response to anesthetics, and whether anesthetics influence the contraction of muscle cells in part through their effects on transport phenomena.

ACKNOWLEDGMENT

The author (L.A.) is indebted to Dr. J. S. Gravenstein for his encouragement and assistance during the preparation of this manuscript.

HALOTHANE AND REDUCED HEPATIC BLOOD FLOW. The authors describe marked reductions in hepatic arterial flow during angiographic studies performed under halothane anesthesia. A 4-year-old female with neurofibromatosis undergoing a renal arteriogram was noted to have poor visualization of the hepatic arteries distal to the common hepatic artery and perfusion of the right liver lobe was minimal. In the previous 18 months this child had received four uneventful halothane anesthetics for nonabdominal procedures. A second patient (3-year-old female) manifested similar slowing of hepatic arterial flow which returned to normal 25 minutes after discontinuing halothane and substituting nitrous oxide and d-tubocurarine. Neither patient manifested clinical or biochemical evidence of postanesthesia liver dysfunction. A subsequent review of 25 aortograms performed with halothane anesthesia revealed slowing of hepatic arterial flow in 8 patients (32%). Halothane may produce an increase in vasomotor tone specific to hepatic circulation while sparing arterial flow to other abdominal viscera. The marked slowing of hepatic arterial flow by halothane may reflect increased vasomotor tone primarily at the hepatic arterial, sinusoidal or venous levels. *(Burger PE, Culham JAG, Fitz CR et al: Slowing of hepatic blood flow by halothane: Angiographic manifestations. Radiology 118:303-306, 1976)*

Methoxyflurane Biotransformation and Renal Function Following Methoxyflurane Administration for Vaginal Delivery or Cesarean Section

STEVEN R. YOUNG, MD*
ROBERT K. STOELTING, MD†
VIRGINIA K. BOND, MD‡
CHRISTINE PETERSON, RN§
Indianapolis, Indiana‖

Methoxyflurane (MOF) administration for conscious analgesia during vaginal delivery (range 5 to 70 min, mean 23 min) or for anesthesia following delivery of the infant at cesarean section (range 25 to 70 min, mean 44 min) was studied in 18 healthy parturients. Serum ionic fluoride increased significantly in both groups 2 hours after discontinuing MOF with peak concentrations of 11.2 and 14.1 μmol/L in the vaginal delivery and cesarean section groups, respectively. Individual peak serum ionic fluoride levels in the 2 groups of 21 and 25 μmol/L were well below reported levels for subclinical toxicity. Significant ionic fluoride elevations in fetal umbilical venous blood (mean 5.3 μmol/L) were measured in the vaginal-delivery group. Maternal urinary ionic fluoride and oxalate were elevated 24 and 48 hours postpartum. BUN, creatinine, urine volume, and urine osmolality remained within normal range. These data indicate that hazardous elevations of serum ionic fluoride with subsequent renal dysfunction are unlikely following low-dose MOF administration for vaginal delivery or cesarean section.

NUMEROUS reports have appeared documenting the association between methoxyflurane (MOF) biotransformation to ionic fluoride and oxalate and postoperative renal dysfunction.[1,2] Nevertheless, MOF administration during vaginal delivery or cesarean section provides good maternal analgesia without significant effects on uterine tone. Documentation that low-dose MOF administration does not result in hazardous serum ionic fluoride elevations would be useful. Indeed, large increases in serum ionic fluoride do not usually occur following awake MOF analgesia during labor and vaginal delivery.[3]

In the present study, MOF biotransformation and renal function were determined in two groups of healthy parturients who received MOF either for conscious analgesia during vaginal delivery only or after delivery of the infant at cesarean section.

METHODS

During vaginal delivery, 11 patients received pudendal nerve blocks and conscious

Paper received: 7/7/75
Accepted for publication: 8/14/75

analgesia with MOF (0.2 to 0.5% Pentamatic® vaporizer settings) delivered in O_2, 5 L/min via a semiclosed-circle absorption anesthetic system. Administration was continuous or intermittent, as determined by the patient's ability to respond to verbal commands.

The second group of 7 patients for elective cesarean section received 4 mg/kg of thiamylal and 60% N_2O in O_2 plus succinylcholine for skeletal muscle paralysis until delivery of the infant. Following delivery, anesthesia was maintained with MOF (0.2 to 0.5% Pentamatic vaporizer settings) plus 60% N_2O at a total gas flow of 5 L/min via a semiclosed-circle absorption anesthetic system.

Mothers with renal or hepatic disease, preeclampsia, or history of drug intake (other than supplemental iron and vitamins) were excluded from this study.

Venous blood samples for serum ionic fluoride were obtained from all mothers before MOF administration (control), at delivery (vaginal delivery group), 1 hour after discontinuing MOF (cesarean-section group), and in all patients 2, 24, and 48 hours after MOF administration. Samples were also obtained from the umbilical vein of all infants in the vaginal-delivery group at the time of delivery. Serum creatinine, blood urea nitrogen (BUN), serum uric acid, and serum osmolality were determined before delivery and 24 and 48 hours postpartum. Ionic fluoride was measured with a fluoride ion-specific electrode.[4] Oxalate was measured by Bio-Science Laboratories.[5]

Umbilical vein and maternal arterial samples were collected in glass syringes at delivery and analyzed for MOF concentration by gas chromatography after extraction into tetrachloroethylene.[6]

Maternal 24-hour urine collections for ionic fluoride, oxalate, osmolality, and total volume were initiated at delivery and continued for 48 hours.

Newborn condition at birth was ascertained by 1 and 5-minute Apgar scores and by time to sustained respirations.

Data were analyzed by Student's *t*-test, $p<0.05$ being considered significant.

RESULTS

Maternal groups were similar with respect to age (mean 28 years) and weight (mean 68 kg). The average duration of MOF administration was different: 23 minutes (range 5 to 70) in the vaginal-delivery group and 44 minutes (range 25 to 70) in the cesarean-section group.

Serum ionic fluoride increased significantly in all patients following MOF administration (tables 1 and 2). Peak ionic fluoride levels were 11.2 ± 1.4 μmol/L and 14.1 ± 2 μmol/L at 2 hours after discontinuing MOF for vaginal delivery or cesarean section, respectively. Ionic fluoride concentrations decreased, but were still significantly elevated above control levels, 24 and 48 hours postpartum. In 2 of 7 patients following cesarean section, serum ionic fluoride concentrations 3 hours after discontinuing MOF were similar to the 2-hour determinations. This suggested that the serum ionic fluoride elevations after 2 hours accurately reflected maximum fluoride elevations in this group.

At vaginal delivery, fetal umbilical vein ionic fluoride concentrations were 5.3 ± 0.7 μmol/L compared with 7.1 ± 0.8 in the mothers. Maternal MOF concentrations following vaginal delivery were greater than the corresponding fetal umbilical vein concentration (2.1 ± 0.4 mg/100 ml versus 1.5 ± 0.3 mg/100 ml). These arterial values corresponded to alveolar concentrations equal to 0.025 vol/100 ml and 0.018 vol/100 ml, respectively, assuming a blood-gas partition coefficient equal to 13 for mother and infant.

Significant increases, although still within the normal range for our laboratory, were seen in BUN at 24 and 48 hours in the vaginal-delivery group and in serum creatinine at 48 hours in the cesarean-section group (table 1).

Urinary excretion of ionic fluoride and oxalate were maximally elevated on the 1st day following delivery in both groups (table 3). Maternal urine volumes and urine osmolality were within normal range 24 and 48 hours postpartum.

Apgar scores were greater than 7 and 8 after 1 and 5 minutes, respectively, in the vaginal-delivery group infants, except in one 1.8 kg infant whose scores were 5 and 8. Time to sustained respiration was less than 60 seconds in all infants.

DISCUSSION

Serum ionic fluoride levels capable of producing dose-related renal dysfunction after MOF administration have been documented

TABLE 1
Maternal Laboratory Values (Means ± SE)
(Numbers of Determinations in Parentheses)

Test	Control	Delivery
Serum ionic fluoride (μmol/L)		
Vaginal delivery	2.7 ± 0.3 (11)	7.1 ± 0.8 (10)*
Cesarean section	2.6 ± 0.6 (7)	
Serum creatinine (mg/100 ml)		
Vaginal delivery	0.65 ± 0.06 (10)	0.65 ± 0.06 (10)
Cesarean section	0.63 ± 0.04 (6)	
Blood urea nitrogen (mg/100 ml)		
Vaginal delivery	6.4 ± 0.6 (10)	6.0 ± 0.6 (10)
Cesarean section	7.3 ± 1.0 (6)	
Serum uric acid (mg/100 ml)		
Vaginal delivery	4.9 ± 0.3 (10)	4.9 ± 0.3 (10)
Cesarean section	4.9 ± 0.5 (6)	
Serum osmolality (mOsm/L)		
Vaginal delivery	265 ± 2 (10)	267 ± 3 (11)
Cesarean section	270 ± 5 (4)	
MOF (mg/100 ml—vaginal delivery)		
Maternal arterial		2.1 ± 0.4 (11)
Fetal umbilical venous		1.5 ± 0.3 (9)

		263 ± 3 (5)	269 ± 6 (5)

by Cousins and Mazze.[2] For example, peak serum ionic fluoride concentrations above 50 μmol/L may be associated with subclinical toxicity manifested by delayed return to maximum preoperative urine-concentrating ability and increased serum uric acid. Serum ionic fluoride concentration above 90 μmol/L may produce further evidence of renal dysfunction: polyuria, high serum osmolality, hypernatremia, and low urine osmolality.

In this study, maximum serum ionic fluoride elevations after conscious analgesia during vaginal delivery (11.2 μmol/L) or after short-term administration for cesarean section (14.1 μmol/L) were far below levels

TABLE 3
Maternal Urinalysis Results (Means ± SE)
(Number of Determinations in Parentheses)

Test	Hours after discontinuing MOF	
	24 hours	48 hours
Urinary ionic fluoride (μmol/L)		
Vaginal delivery	504 ± 55 (9)	350 ± 48 (9)
Cesarean section	2072 ± 775 (3)	908 ± 196 (3)
Urinary oxalate (mg/24 hr)		
Vaginal delivery	83.4 ± 16.1 (9)	54.5 ± 13.1 (9)
Cesarean section	69.5 ± 2.5 (2)	39.7 ± 37 (2)
24-hour urine volume (ml)		
Vaginal delivery	2999 ± 432 (10)	1853 ± 330 (10)
Cesarean section	2140 ± 360 (3)	1825 ± 25 (3)
Urinary osmolality (mOsm/L)		
Vaginal delivery	299 ± 38 (10)	386 ± 31 (10)
Cesarean section	442 ± 73 (3)	359 ± 18 (3)

associated with detectable renal dysfunction.[1,2,7] Indeed, the highest individual elevation in the group receiving conscious analgesia was 21 μmol/L (after 17 min of MOF administration), while 25 μmol/L was the highest single value reported in a cesarean-section patient (after a 50-min exposure).

Some patients with higher arterial MOF concentrations or longer periods of exposure actually had lower serum levels of ionic fluoride, suggesting individual variability of MOF biotransformation. As would be expected with a dose-related response, concentrations following more prolonged awake MOF analgesia (mean 127 min) for both labor and vaginal delivery were greater (21.9 μmol/L)[3] than those found in this study. Furthermore, 2 patients manifested concentrations above 50 μmol/L with this more prolonged administration.[3]

Blood urea nitrogen or serum creatinine increased ($p<0.05$) following MOF administration, but these elevations did not exceed the normal range. Similar changes were reported by Creasser's group,[3] but another report[8] did not show any increase in BUN after MOF analgesia. Some renal-function changes might not have been observed, since early MOF-induced renal dysfunction is a concentrating defect,[2] and specific stress for concentrating ability was not tested.

A maternal artery-umbilical vein MOF difference was present at vaginal delivery: 2.1 mg/100 ml maternal versus 1.5 mg/100 ml fetal. This fetal MOF concentration was not associated with fetal depression as measured by Apgar scores or time to sustained respirations. Other reports[3,9] have demonstrated that maternal artery-fetal umbilical vein MOF gradients diminish with more prolonged MOF administration.

Mean serum ionic fluoride in the fetal umbilical vein at delivery was 5.3 μmol/L, compared with a maternal level of 7.2 μmol/L. (Infants born to mothers with no MOF administered have mean serum ionic fluoride levels of approximately 1 μmol/L.)[3] Increased fetal serum ionic fluoride levels would most likely be the result of transplacental fluoride diffusion or the consequence of MOF biotransformation in utero, though the degree of biotransformation could be limited by poorly developed neonatal microsomal enzymes.[10] What effects increased ionic fluoride have on the immature kidney is largely unknown. Other studies[11,12] have found maternal and fetal serum levels of ionic fluoride similar to those in this report.

Urinary excretion of fluoride and oxalate reflected MOF biotransformation. Peak urinary excretion of fluoride (2072 μmol/L) and oxalate (83.4 mg/24 hr) seen on the 1st postpartum day was far below levels reported after more lengthy MOF anesthesia.[13,14]

We conclude that dangerous serum ionic fluoride elevations and subsequent renal dysfunction are unlikely when low-dose MOF is administered for conscious analgesia during vaginal delivery or for short durations

following delivery of the infant at cesarean section.

50th Congress Report

March 14-18, 1976

Phoenix, Arizona

THE 50th Congress of the International Anesthesia Research Society, a long-planned, milestone celebration in our history, was held in Phoenix, Arizona, March 14-18, 1976.

The meeting was originally scheduled for Caesars Palace in Las Vegas, Nevada, but an unexpected labor strike there necessitated its move to the Hyatt Regency Hotel/Civic Plaza in Phoenix three days prior to the scheduled opening. We very much regret the inconvenience this caused to those who did attend, and the disappointment of those who could not. (For an "inside" view of the meeting transfer as well as "outside" reaction, see "Chronicle of the 50th Congress—Location Change" on page 428 and correspondence following.)

Fifty-seven papers encompassing the broad spectrum of anesthesiology were presented. For the first time, the program committee ran simultaneous sessions. We hope this new format, of simultaneous sessions, was acceptable and we would appreciate your comments.

Eighty-two technical and scientific exhibits, all interesting and educational, each manned by a knowledgeable attendant, provided a rich source of information.

Prizes were awarded to three of the scientific exhibits for their excellent presentation of their particular subject matter.

First Prize: *Obstetric Anesthesia and the Newborn,* Gerard W. Ostheimer, M.D., and associates, Boston Hospital for Women and Harvard Medical School.

Second Prize: *Anticholinergic Differences —A Matter of Safety,* Alon P. Winnie, M.D., University of Illinois Hospital.

Third Prize: *American Independence—Anesthesia or Anaesthesia? Bicentennial Observations,* Keith Murrin, M.B., and coworkers, University of North Carolina.

Dr. Leroy David Vandam, Professor of Anaesthesia, Harvard Medical School and Anesthesiologist-in-Chief of the Peter Bent Brigham Hospital, Boston, Massachusetts, presented the Eleventh Annual Becton-Dickinson & Company Oscar Schwidetzky Memorial Lecture entitled "On the History of Ideas in Anaesthesia." Dr. Vandam's

reputation filled the lecture hall with an expectant audience. They were well rewarded. His paper will appear in the July-August issue of this journal.

The Fourteenth Annual Baxter-Travenol Lecture entitled "Epidemiologic Answers to Laboratory Questions in Environmental Cancer" was delivered by Dr. Irving J. Selikoff, Professor of Medicine, Director, Environmental Sciences Laboratory, Mount Sinai School of Medicine, New York, New York. Dr. Selikoff is internationally known for his many contributions to environmental health, a subject of great importance to everyone. His very educated presentation provided valuable information on a subject about which too many of us know too little. This paper will appear in the September-October issue of *Anesthesia and Analgesia.*

Our well attended Golden Anniversary Commemorative Luncheon was held on Tuesday noon, presided over by Dr. Kenneth K. Keown, Chairman of our Board of Trustees. He introduced our guests, Dr. John Ditzler, President, American Society of Anesthesiologists, and Dr. John H. A. Lawrence, President, Canadian Anaesthetists' Society. Both Dr. Ditzler and Dr. Lawrence expressed their pleasure and carried friendly greetings to us from their respective societies.

Dr. T. H. Seldon, Member of the Board of Trustees of the International Anesthesia Research Society and Editor of *Anesthesia and Analgesia . . . Current Researches* presented a brief history of the Society pointing out that Dr. McMechan, Founder of this Society, and first Editor of *Anesthesia and Analgesia* and Mrs. McMechan probably have done more for our specialty than most of us will ever realize.

The highlight of the luncheon was a presentation by Dr. B. B. Sankey, our Executive Secretary, of a check for $10,000 to Dr. John Ditzler for the Committee on Research of the American Society of Anesthesiologists to commemorate the 50th Anniversary of the International Anesthesia Research Society. (See Correspondence on page 426.)

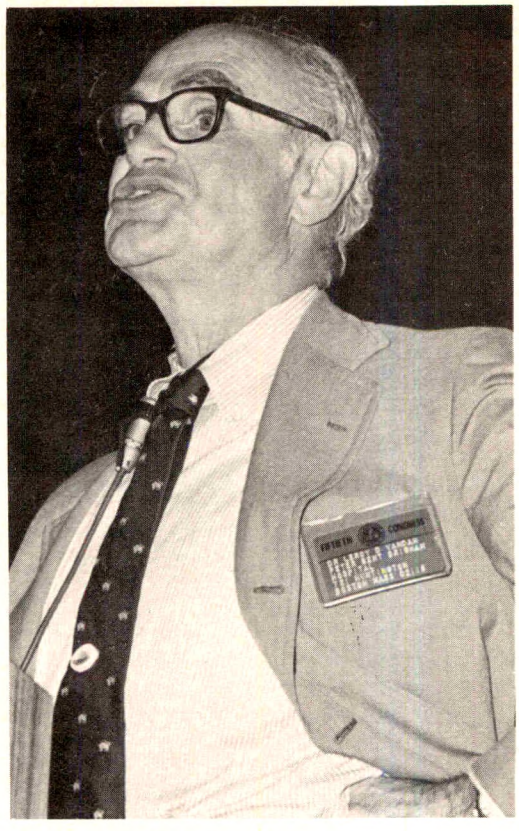
The members of the International Anesthesia Research Society are pleased to have participated in this gesture and look forward to seeing the results that follow the use of this money.

The Sunday evening social hour and the coke and coffee breaks during the scientific sessions again provided opportunities to renew old friendships, make new acquaintances, and discuss subjects of mutual interest.

The 51st Congress will be held at the Diplomat Hotel, Hollywood, Florida, on March 6-10, 1977.

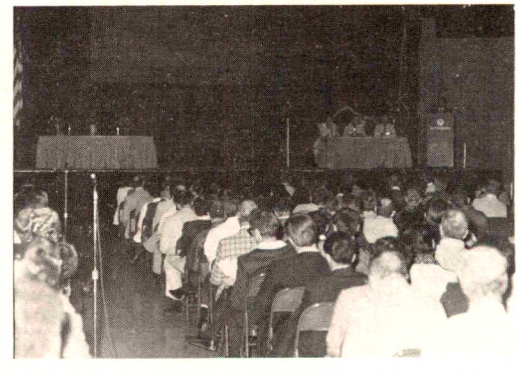
Titles and abstracts of papers to be considered for presentation must be in the hands of the program committee no later than August 2, 1976.

Abstract forms may be obtained from the Program Chairman, John T. Martin, M.D., Department of Anesthesiology, Medical College of Ohio, Toledo, Ohio.

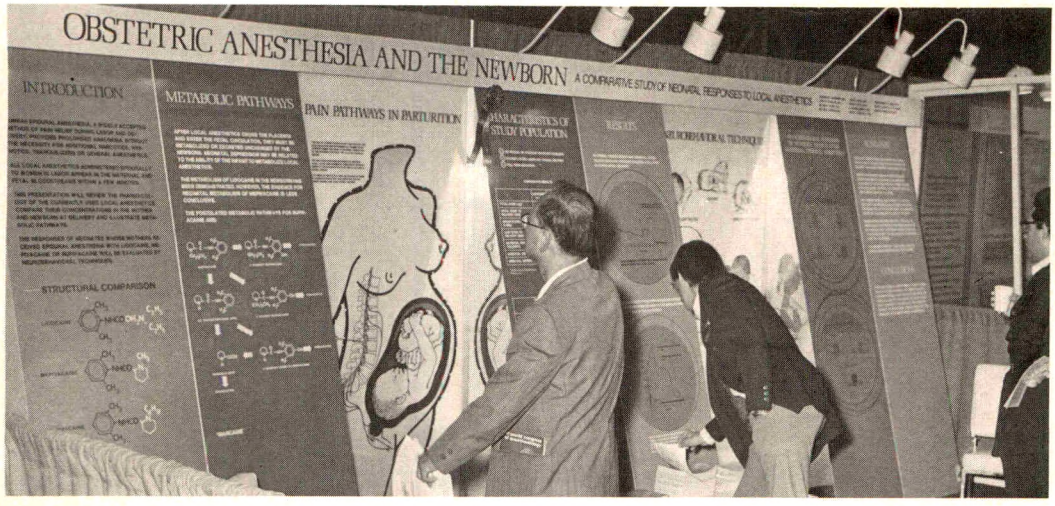


Dr. Leroy D. Vandam, was the Eleventh Annual Becton, Dickinson and Company Oscar Schwidetzky Memorial Lecturer. His presentation was entitled "On the History of Ideas in Anaesthesia."

Dr. Irving J. Selikoff, was the Fourteenth Annual Baxter-Travenol Lecturer. His presentation was entitled "Epidemiologic Answers to Laboratory Questions in Environmental Cancer."

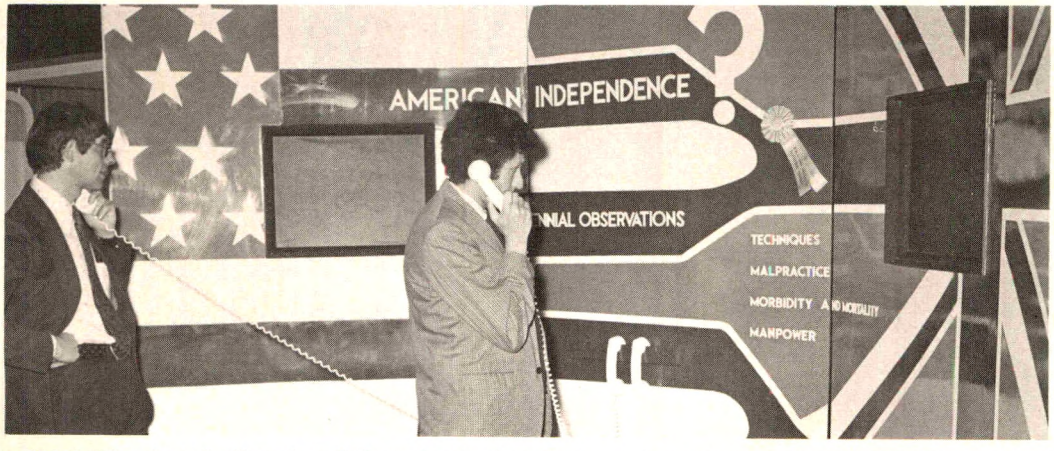


The Panel "Anesthesia for the Patient with Cardiac Disease" was well attended and very informative.



First Prize Award. "Obstetric Anesthesia and the Newborn." Gerard W. Ostheimer, MD and Associates.

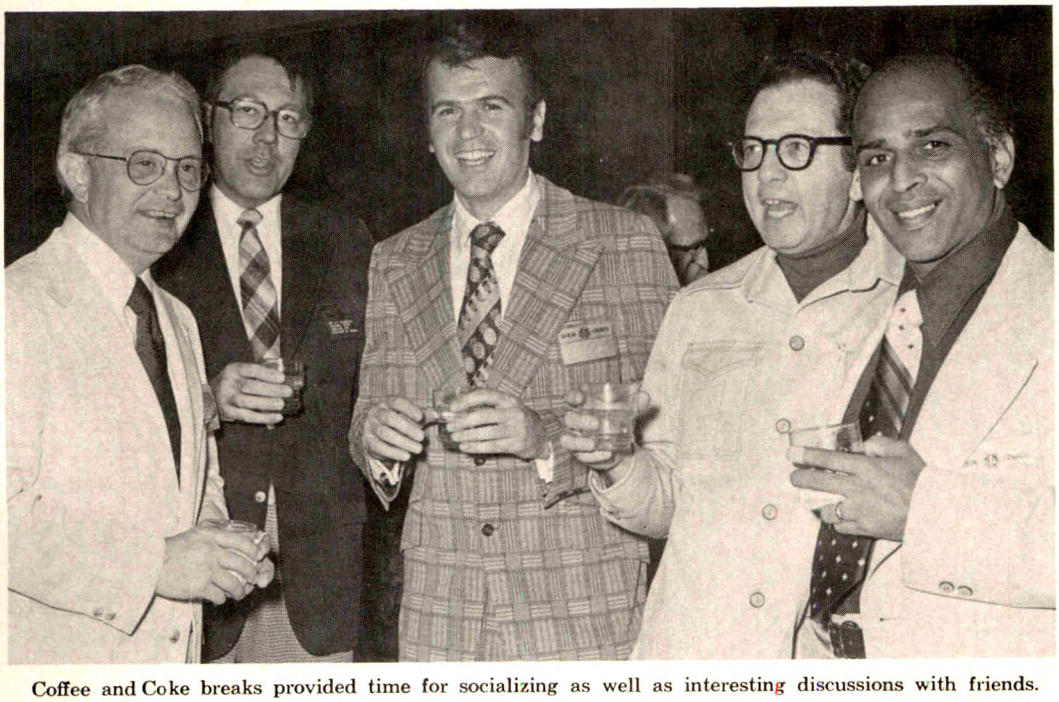
Second Prize Award. "Anticholinergic Differences —A Matter of Safety." Alon P. Winnie, MD.



Third Prize Award. "American Independence—Anesthesia or Anaesthesia? Bicentennial Observations." Keith Murrin, MB and Associates.

Sunday afternoon was a busy day for registration.

Intermission times were used to visit the technical and scientific exhibits.



Coffee and Coke breaks provided time for socializing as well as interesting discussions with friends.

Dr. B. B. Sankey, Executive Secretary of the International Research Society (right) presented a check for $10,000 for research to Dr. John Ditzler, President of the American Society of Anesthesiologists.

Kenneth K. Keown, M.D.
Chairman, Board of Trustees

Dear Doctor Keown:

This will officially acknowledge the receipt of the International Anesthesia Research Society's check in the amount of $10,000 made payable to the American Society of Anesthesiologists in behalf of its Committee on Research. It is my understanding that this is a commemorative donation in the interests of our mutual interest in research and the young investigators who produce the papers which appear from time to time on the IARS program as well as ASA. I am personally greatly appreciative of the confidence IARS has shown in ASA through this donation. I am particularly pleased that this donation could occur at a time when my life-long friend, Paul Dumke, was being honored in his final meeting as a Member of the Board of Trustees and when I was President of the ASA.

John W. Ditzler, M.D., President,
The American Society of Anesthesiologists

To the Board of Trustees and
Program Committee

Gentlemen:

I would like to thank the members of the Board of Trustees for the faith you have shown in the Committee on Research of the ASA by presenting them with the gift of $10,000. I am especially interested in this project, and feel that the future of anesthesia research is being developed at the present time and that this is one of the most efficient and effective ways that all of us can utilize to try to develop future investigators. The fact that the International Anesthesia Research Society felt that this would be an appropriate way to celebrate your fiftieth anniversary is to me a most significant milepost in the belief of a very outstanding group of people in the future of anesthesia research. You have my sincere and heartfelt congratulations, and my personal commendation for a significant contribution to the future of anesthesia research.

Evan L. Frederickson, M.D.
Professor
Anesthesiology and Pharmacology
Emory University
Atlanta, Georgia

Kenneth K. Keown, M.D.
Chairman, The Board of Trustees

Dear Ken,

Never have I witnessed or, for that matter, ever heard of a munificent gift on the order of that from the International Anesthesia Research Society to the American Society of Anesthesiologists. What a grand and generous thing to do!

Please accept from me the gratitude of the Scientific Council of the ASA for this magnificent gesture from one great organization to another.

Robert T. Patrick, M.D.
Vice President for Scientific Affairs
The American Society of Anesthesiologists

Chronicle of the 50th Congress
Location Change
March 7-14, 1976

LAS VEGAS' legendary Jimmy the Greek is probably thanking his lucky vegas that he didn't make "book" on the strike that moved the 50th Congress from his domain in Las Vegas to Phoenix, Arizona, to say nothing of quoting odds on the same meeting being "struck out" twice in the same city by the same union. Happen it did, however, and despite the fates that conspired against us, the meeting opened on schedule at 1 p.m. on Sunday, March 14th, and it turned out to be not only the sentimental milestone we had planned, but also a small psychological triumph.

For the many who were amazed and gratified at the expeditious transfer, this chronology of the "week that was" will be interesting. For those who expressed dismay at our "inept" handling of the move, it will hopefully result in a more understanding appraisal of the sequence and timing of events that made it necessary.

The story properly begins in March 1973 when the Las Vegas culinary workers signed a 3-year agreement which included a "no-strike" clause. With that assurance in hand (having had to move our 1970 meeting from Caesars Palace to Palm Springs, California, because of their strike), we finalized the 1976 meeting dates with Caesars Palace.

From that time on, in our many contacts with the hotel, numerous local suppliers and the Convention Bureau, there was not a single hint of a labor problem. We had worked long and hard to make our Golden Anniversary meeting the biggest and best in our history, and on Friday, March 5, when the final programs, preregistration cards and the last of our meeting supplies were shipped from Cleveland to Las Vegas, all systems were GO!

Sunday, March 7th: The first clue comes in an 11 p.m. telephone call to Dr. Seldon in Rochester from Dr. F. Ervin King, an IARS member from Missoula, Montana. He wondered if we still planned to meet in Las Vegas in view of the "probable" strike scheduled for Wednesday, March 10th, by the culinary workers' union. Dr. King's information came from a pediatrician friend in Las Vegas who heard it from the mother of a patient he had recently treated who had a relative in the union. Dr. Seldon immediately relayed the "message from Missoula" to Dr. Sankey in Cleveland, who in turn called the Caesars Palace management—2 a.m. on Monday, March 8th, Las Vegas time. They confirm the expiration of the culinary workers' contract at midnight on Wednesday, but are certain that even if the union turn down the offered contract, they would abide by the no-strike provision while they continued negotiations. So much for the "message from Missoula."

Monday, March 8th—6 a.m. Cleveland. Despite last night's reassuring comments from the hotel and the strong belief (hope?) that it couldn't possibly happen again, nagging memories of the 1970 strike that forced our move to Palm Springs are stirred. "Just in case," Dr. Sankey lists possible alternate meeting sites within a day's trucking distance of Las Vegas (so exhibits could be

moved). First on the list is Palm Springs, our 1970 port in the storm, and he reaches for the telephone which will soon feel like a permanent attachment. Hotel space we needed is not available, and Palm Springs is crossed off. Los Angeles is eliminated next —they have rooms but not adjacent exhibit space. San Diego can take us on March 21st but not on the 14th. Phoenix is last on the list. With a brand new hotel across the street from their Civic Center, they are ready, willing and able to take us if need be. We promise to advise them one way or another at midnight on Wednesday when we hear from Las Vegas. The Board of Trustees of the IARS is advised for the first time, and all of them book alternate travel to Phoenix.

Tuesday, March 9th: Several talks with the Las Vegas Convention Bureau and Caesars Palace management reveal no progress in negotiations. Neither would even speculate on the chances of a strike, but we detect, for the first time, some reservation that the no-strike clause would prevail.

Pending the union decision the next day, we alert all program participants and technical and scientific exhibitors that we may have to move the meeting to Phoenix. If we have to move, we need to know whether the many participants are willing to go along. The overwhelming majority are. Principals of the American Society of Regional Anesthesia, whose inaugural meeting is to follow ours, also are advised. They, too, will "roll with the punches."

The Las Vegas exhibit drayage and decorating contractors are requested to make contingency plans to move and set up exhibits in the Phoenix Civic Plaza.

Since our meeting preregistration cards are already on a truck enroute to Las Vegas, we cannot plan to advise registrants if the meeting is changed. Caesars Palace readily agrees, if necessary, to send telegrams to meeting registrants with reservations at their hotel and to the overflow registration at the MGM Grand hotel.

Wednesday, March 10—midnight in Las Vegas, Thursday, March 11—3 a.m. in Cleveland. Caesars Palace advises that the union vote on the new contract has been postponed until after negotiations are resumed twelve hours later. The hotel feels the situation is serious, but not altogether impossible. In the absence of a clear-cut union decision, the burden is completely on us. H-Hour is here! The consensus after several telephone calls to IARS Board members is: we are determined to hold the 50th Congress so we must move to Phoenix. More telephone calls and all the prearranged contingency procedures are implemented. Six hours later the IARS staff is in the air to Phoenix with 72 hours remaining to revamp our meeting plans and start from scratch with 2 hotels and a separate convention center we had never seen.

Thursday, March 11th—2:30 p.m., Phoenix. Initial misgivings and anxiety give way to relief as the IARS staff is greeted by the Phoenix Convention Bureau staff and taken directly from the airport to a meeting with an enthusiastic delegation from the hotels, civic center and service and supply firms whose assistance is essential to salvaging our meeting. Their sincere interest, concern and know-how is reassuring. We begin to see a rainbow in the Valley of the Sun!

Friday, March 12th: In Las Vegas: The culinary workers vote to strike. Ironically, we are now grateful to them for two reasons. First, the national news coverage will reach the registrants we were unable to contact directly. And, since the decision to move was made before the strike was voted, we now assume the role of foresighted planners —much nicer than the best of the possible alternatives.

The last of five double trucks containing the technical and scientific exhibits is loaded and starts the 250-mile haul to Phoenix. We calculate the cost and are temporarily anesthetized. What price determination! *In Cleveland:* The IARS office telephones are ringing off the hook as the meeting change telegrams are being received all over the country. Unfortunately, the news coverage of the strike has not reached some areas— and is sketchy and confusing in others. Many of the callers are understandably upset and baffled. They're not happy—but "Ma Bell" has no complaints.

In Phoenix: The contract is signed with the Civic Center for meeting and exhibit space; audio-visual equipment is ordered; social functions arranged with the Hyatt Regency; airlines contacted and urged to supplement scheduled service in and out of Phoenix; news services contacted to publicize the Las Vegas strike and our move to Phoenix; housing and reservation details

coordinated with cooperating hotels, who are now checking in the first of our registrants. Caesars Palace management personnel arrive mid-afternoon with a station wagon full of IARS convention supplies, including vital preregistration cards. We are relieved to find everything has come through except the Golden Anniversary souvenir pens. (They finally arrived on Wednesday, the second last day of our meeting.)

Saturday, March 13th: Six registration clerks from the Phoenix Chamber of Commerce assist in embossing, typing and stuffing badges for 1700 preregistrants, including spouses and exhibitors. On completion at 9:30 p.m. there is much speculation on the number of badges that would be picked up.

Exhibit trucks arrive in Phoenix and are uncrated in the Civic Plaza. When the last exhibit is assembled on Sunday afternoon, all are present and accounted for except one —Dr. T. J. Akamatsu's "Ketamine for Parturition" scientific exhibit is missing. It is located two days later—in Reno of all places.

Many more check-ins at the Hyatt Regency and the Adams Hotel. It's working!

Sunday, March 14th: Registration opens on schedule at 1 p.m. and immediately takes on the aura of an army reunion. The "survivors" straggle in with assorted tales of relief, amazement and woe. Someone suggests we attach purple hearts to the gold badges. The bouquets take a decided lead over the brickbats, and we maintain an anxious vigil over the badges that still need to be claimed. Around 4:30 p.m., Dr. Anis Baraka, a program participant from embattled Beirut, Lebanon, checks in and is greeted like a conquering hero. He is amazed at the fuss. "You think you have problems? When I left Lebanon last night, we had two presidents and two armies." At that point, we didn't know whether to laugh or cry with him, but we knew one thing for sure: It had been a "gutsy," hectic, uphill and expensive week for us, and even if nobody else shows up, it was all worth it. The 50th Congress was alive and well—and open for business.

Miss Dorothy Merich,
IARS Cleveland Office

Mrs. Agnes M. Osborn,
Rochester Editorial Office

EPILOGUE

The final program of the meeting included this sentence: "That the 50th Congress is being held today is indeed a monument to the continued vitality of the specialty which supports it." When that was written we had no idea how truly prophetic it was. No matter how determined we were that it would take place, it couldn't have happened without an equal commitment from our members. When we closed the meeting on Thursday, March 18th, we found that professional registration totaled 825 out of 977 pre-registered. Total meeting registration was 1425 vs 1700 preregistered. Another national meeting, also displaced by the Las Vegas strike preregistered 2000 and ended up with 800 attending. We can add nothing to the comparison except our warm appreciation for the wonderful support.

We are especially grateful to Dr. King whose distant early warning from Missoula quite possibly saved the day. We subsequently learned that a commitment was sought for the Phoenix space that we used just five hours after we had secured it.

Outside of the specialty there were a great many others whose interest, concern and hard work were invaluable and should be noted:

Charley Monahan and Bill Tobin of Caesars Palace Hotel for their wholehearted cooperation in effecting the transfer; Ted Sprague, Pam Cash and their numerous assistants at the Phoenix and Valley of the Sun Convention Bureau for their round-the-clock, enthusiastic response to our SOS; Wally Oberlender and his staff at the Hyatt Regency and Ron Lindemann and the Adams Hotel personnel for their efficient handling of our meeting needs and the many courtesies extended to our registrants; Charles B. Slack and the staff of our exhibit management company for their extra efforts and cooperation in overseeing this aspect of the meeting transfer; Denny Maus and the employees of the Phoenix Civic Plaza who were unfailingly cooperative in providing for our meeting needs; Dr. Brian Lockwood at the St. Luke's Medical Center in Phoenix for loaning us some of their audio-visual equipment not otherwise available in the area.

To all of them, our sincere thanks and appreciation.

For the IARS Board of Trustees,
Kenneth K. Keown, M.D., Chairman;
Emerson A. Moffit, M.D., Vice Chairman;
and B. B. Sankey, M.D., Executive Secretary.

To the Board of Trustees and Program Committee:

I want to congratulate you and your staff for successfully moving the International Anesthesia Research Society Meeting so smoothly from Las Vegas to Phoenix. Everyone was amazed at the painless, effective transition.

Also, I would like to comment upon two significant events at the Fiftieth Congress of the International Anesthesia Research Society. I thought the $10,000 contribution to the ASA for furthering research was generous and is certainly timely. I think the change in format to running simultaneous presentations did successfully enhance the value of the meeting by broadening the scope of presentations and increasing the number of worthwhile papers.

J. G. Reves, MD

Pharmacology
University of Alabama Medical Center
Birmingham, Alabama

To the Board of Trustees and Program Committee:

I would like to express my appreciation for the great effort and excellent performance which occurred in transferring our 1976 meeting from the scheduled site in Las Vegas to the actual site, Phoenix, Arizona. The smoothness and efficiency with which this change was implemented stands as a tribute to both the Board of Trustees and the Program Committee and indicates that our society remains active, useful and responsive to the needs of its membership. I feel privileged to be counted as a member.

50th Congress Technical Exhibitors

A note of thanks to the following 63 companies for their support of our Golden Anniversary meeting. Despite the confusion and inconvenience of the last-minute move from Las Vegas to Phoenix, 58 of the exhibits were staffed and "open for business" to a most appreciative audience. The I.A.R.S. Board of Trustees is especially grateful for their understanding cooperation.

Case History Number 90:

Cardiac Decompensation During Enflurane Anesthesia in a Patient with Myotonia Atrophica

MICHAEL B. MEYERS, MD*
PAUL G. BARASH, MD†
New Haven, Connecticut‡

THE patient, a 43-year-old, 83 kg man, was admitted to the hospital with the chief complaint of nonradiating right upper quadrant and midepigastric tenderness. Physical findings consistent with myotonic dystrophy, noted 4 years before, were also present at this admission.

Vital signs and laboratory data, including hemogram and liver profile, were normal. Serum K^+ was 3.3 mEq/L (normal = 3.6 to 5.5 mEq/L); other serum electrolytes were within normal range. Chest x-ray was normal and ECG demonstrated a 1st-degree heart block. Arterial blood gases (F_{IO_2} = 0.21) were: pH 7.56, P_{aCO_2} 22 torr, P_{aO_2} 76 torr.

On the 4th hospital day, the patient was premedicated with 10 mg of morphine sulfate, 100 mg of secobarbital, and 0.5 mg of atropine IM. One hour later, on admission to the operating room for cholecystectomy and common bile duct exploration, his vital signs were arterial blood pressure (BP) 130/90 torr, pulse 80 bpm and respirations 15/minute. Anesthesia was induced with 180 mg of thiopental IV and N_2O (70%) in O_2 supplemented with enflurane (2% inflow concentration into the circle system). The trachea was intubated without the use of muscle relaxants.

Following induction, anesthesia was maintained with N_2O (60%) in O_2 with enflurane (2%). Ten minutes later under controlled ventilation, the pulse rapidly decreased to 70 bpm and systolic BP decreased to 50 torr. The patient was given 0.5 mg of atropine IV without response. Enflurane was discontinued and 30 mg of mephentermine IV was administered in divided doses. Within 1 minute, the BP rose to 150/90 torr and pulse to 110 bpm. A radial artery catheter and pulmonary artery flow-guided catheter were introduced percutaneously.

Pulmonary capillary wedge pressure was 10 torr and cardiac output was 5.2 L/min (thermodilution). Arterial blood gases (F_{IO_2} = 0.5) were: pH 7.40, P_{aCO_2} 29 torr, P_{aO_2} 70 torr. The pulmonary capillary wedge pressure remained stable for 90 minutes. Lactated Ringer's solution was infused at a rate of 8 to 10 ml/kg/hr during the first 90 minutes.At this time, the ECG recorded a right bundle branch block and the pulmonary capillary wedge pressure was noted to have increased to 22 torr (BP 110/60 torr). Arterial blood gases (F_{IO_2} = 0.5) were: pH 7.59, P_{aCO_2} 19 torr, and P_{aO_2} 87 torr. Cardiac output was 4.5 L/min. Following furosemide (40 mg IV), the pulmonary capillary wedge pressure returned to

12 torr (BP 120/70) during the next 30 minutes. The remainder of the 4-hour anesthetic procedure was uneventful.

At the completion of the operation, the patient was admitted to the Surgical Intensive Care Unit (ICU), where ventilation was assisted by a volume-limited ventilator. A 12-lead ECG recorded a right bundle branch block with anterior T wave inversion, which was interpreted as either "secondary to the right bundle branch block or ischemia." Postoperative chest x-ray was within normal limits. Cardiac output was 9.5 L/min, pulmonary capillary wedge pressure was 5 torr, and BP was 170/90 torr. Three hours later, tracheal extubation was accomplished and 40% O_2 given by mask.

On the 1st postoperative day, the patient's condition was stable. The ECG revealed disappearance of the right bundle branch block and T wave inversion with return to preoperative 1st-degree heart block. He was discharged from the ICU after 3 days and from the hospital 15 days postoperatively.

DISCUSSION

Myotonic dystrophy is associated with unexpected perioperative morbidity and mortality.[1] Although there are numerous studies of respiratory function pertaining to operative management, there has been little focus on the cardiovascular stability of these patients in the anesthetized state.

Cardiac abnormalities are becoming increasingly appreciated in this disease as a concomitant to the skeletal muscle disorder.[2] Although cardiac manifestations usually occur relatively late in the course of the disease, they may precede clinical recognition of the primary disease process.[3] The ECG most commonly reflects conduction abnormalities, i.e., atrioventricular delay and/or aberrant intraventricular impulse propagation.[4] Disturbances of rhythm, especially bradycardia, are frequently noted.[5] Furthermore, ECG and vectorcardiographic (VCG) changes simulating myocardiac infarction have been reported.[6,7]

Cardiac catheterization in unanesthetized patients has revealed elevated right ventricular, pulmonary artery diastolic and pulmonary capillary wedge pressures.[8,9] To our knowledge, there has been no prior report of abnormalities of pulmonary artery pressures in the anesthetized subject. There is little correlation between the extent of musculoskeletal impairment and cardiovascular reserve in these patients. The etiology of the cardiac dysfunction has been theorized to be a genetically determined biochemical abnormality,[5] a degenerative cardiomyopathy,[10] or a combination of the latter with ventilatory insufficiency.[8] Fearrington and associates[7] hypothesized that sudden death, which is common in myotonic dystrophy, may be due to cardiovascular causes secondary to the cardiomyopathy seen in over 50% of cases studied at autopsy.

Preoperatively, the ECG, exercise testing, and VCG can be used to evaluate these patients. Continuous intraoperative and postoperative monitoring of the ECG and arterial BP is recommended. Since these patients can have associated degenerative cardiomyopathy, it is reasonable to assume they may exhibit varying degrees of left ventricular dysfunction. Thus, in addition, pulmonary artery pressure monitoring should be considered, since left ventricular dysfunction may elude clinical or laboratory detection.

Comment

EDWIN S. MUNSON, MD

The cardiorespiratory abnormalities associated with the muscular dystrophies are of particular concern to the anesthesiologist. Last year, an article in this Journal by Ravin and colleagues (Anesth & Analg 54:216-218, 1975) discussed the anesthetic management of such patients and emphasized the increased sensitivity of the respiratory system to anesthetic agents. Although cardiac arrhythmias, ECG abnormalities, and even sudden death have been observed for over half a century, few reports of cardiac complications have appeared in the anesthetic literature.

This month's Case History represents a well-documented report of cardiac decompensation during enflurane anesthesia. This case history discusses various aspects of the cardiac pathophysiology and gives recommendations regarding the clinical management of myotonia atrophica patients.

Comment

GEORGE M. SAVIELLO, MD
Department of Anesthesiology
University of Florida
Gainesville, Florida

It has long been known that the cardiovascular system may be involved in myotonic dystrophy. Since the first report in 1912 of marked bradycardia and irregular cardiac action, there have been several reports concerning involvement of the cardiovascular system.[1] The incidence of ECG abnormalities ranges from 40 to 70 percent.[2,3] The principal abnormality detected has been an alteration of the P-R interval, mainly some variety of heart block. This alteration in the ECG is frequently present in the absence of any clinical symptoms. It has, in fact, been the means of diagnosis of an early case of myotonic dystrophy.[3]

There have been few reported cases of clinicopathologic correlation between the ECG and autopsy specimens.[4,5] Of these few, it appears that an infiltrative process of some type is responsible for the conduction defects. Coronary vasculature appears to be fairly well maintained. This causes a cardiomyopathy, frequently observable on VCG, and very often neglected clinically.

It is well established that these patients may have significant respiratory problems due to myotonia and muscle wasting.[6] It is now also obvious that they may have significant cardiovascular problems, with minimal or absent symptoms and laboratory evidence. Perhaps the reason these patients do not get into trouble is that muscle weakness limits activity and strain on the cardiovascular system.

Such patients must be anesthetized with extreme care. Careful attention should be paid to ventilation and airway management, and postoperative mechanical ventilation must be available. It would be prudent to assume that all patients have some degree of cardiomyopathy. Therefore, a technic should be used which has minimal effects upon the cardiovascular system. The potent inhalational agents with their myocardial-depressant properties should be avoided; a "balanced" N_2O-O_2 anesthetic, supplemented with narcotics to avoid the use of muscle relaxants, would be a logical choice. The selection and administration of anesthesia to these patients should be made with the same thoughtfulness and care as for patients with coronary artery disease.

Texas Medical Center
Houston, Texas

Doctors Meyers and Barash are to be complimented for bringing to our attention this observation of altered intracardiac impulse conduction and associated hemodynamic deterioration while anesthetizing a patient with myotonic dystrophy.

The sequence of electrocardiographic events described in this case history suggests a responsible anesthetic-related electrophysiologic conduction alteration. Two previous reports[1,2] indicate that intracardiac conduction is prolonged by both halothane and methoxyflurane in normal dogs. Unfortunately, similar measurements have not been performed with enflurane in either normal or myogenic animal models. Thus, one can only speculate that in this patient, enflurane suppressed conduction sufficiently to produce right bundle branch block and resultant hemodynamic deterioration. The observation that discontinuation of enflurane and administration of atropine and mephentermine increased heart rate sufficiently to restore adequate cardiac output, and that this favorable chronotropic response occurred despite a temporary persistence of the conduction deficit, should be borne in mind by those faced with a similar situation. In the event of an atropine-resistant bradycardia, IV isoproterenol infusion or transvenous ventricular pacing might be required.

Hopefully, in the near future, comprehensive data will be available defining the effects of all currently used anesthetic combinations on intracardiac conduction. This information should permit improved anesthetic management of patients with heart block of many etiologies and, in particular, that group in which the conduction alteration is a part of the myotonic dystrophy syndrome.

Comment

MARTIN D. SOKOLL, MD
Department of Anesthesia
University of Iowa Hospitals
Iowa City, Iowa

Myotonic dystrophy is usually thought to be a disease affecting principally skeletal muscle. There is, however, increasing evidence of cardiac involvement in most, if not all, patients with this disease.[1] Patients with this dystrophy often die suddenly. Caughey and Myrianthopoulos[2] attribute this to the sudden development of lethal arrhythmias. Likewise, these patients are known to develop sudden bouts of congestive failure without other predisposing cause.[1,2]

On the standard ECG, the commonest abnormality noted in patients with myotonic dystrophy is some type of conduction defect. This abnormality is seen in at least 50% of such patients. Griggs' group[3] inserted both His-bundle recording electrodes and atrial-pacing electrodes in 11 patients with this disease. Three patients had normal ECGs, while the remaining 8 had obvious conduction defects. All 11 patients developed Wenckebach phenomenon at rates of 140 bpm or less. This is considered an abnormally slow rate for the appearance of conduction defects. These data strongly suggest that all patients with myotonia dystrophica have either overt or latent conduction abnormalities.

Defective Disposable Endotracheal Tube

TAI-MAO CHIU, MD*
ELSIE F. MEYERS, MD†
St. Louis, Missouri‡

IN THE past few years, sterile disposable polyvinyl-chloride endotracheal tubes have been widely utilized with a good safety record. Complications have included damage to tissues caused by polymers and elastomers, problems with the cuffs, and defective material within the lumen.[1-4]

We recently encountered a new hazard: the punched-out area forming the Murphy eye was still in situ (figure). This irregularity was noted prior to intubation. On application of pressure, the punched-out piece came loose and fell into the lumen of the tube. Vigorous tapping was required for dislodgement.

This report is a reminder of the importance of careful inspection of endotracheal tubes in order to avoid introduction of an endotracheobronchial foreign body.

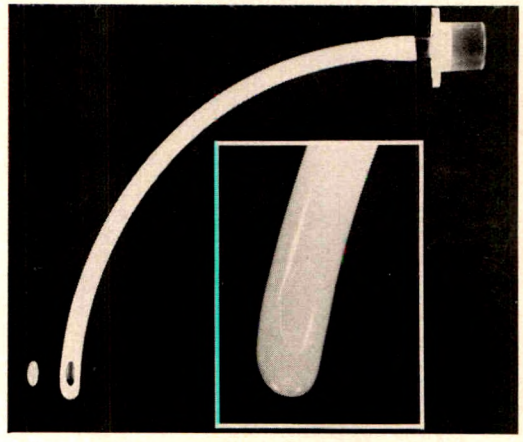

FIGURE. The punched-out area forming the Murphy eye: a possible foreign-body hazard.

Fatal Complication from Swallowed Denture Following Prolonged Endotracheal Intubation: A Case Report

GUNNAR A. KROESEN, MD*
BRUNO C. HAID, MD†
Innsbruck, Austria‡

A 49-YEAR-OLD woman was involved in a traffic accident and suffered shock, cerebral concussion, bilateral maxillary fractures, basal skull fracture, and multiple lacerations of the legs. During the first 2 weeks of her hospitalization, the patient remained intubated with a #8 disposable polyethylene cuffed orotracheal tube. The cuff was only intermittently inflated. The patient was extubated on the 13th day.

Immediately after extubation, she developed mild laryngeal stridor, which responded well to cortisone and calcium therapy. Within 3 hours, the patient was breathing easily and spontaneously, although she was still unable to speak.

Five hours later, while her nurse was performing oral toilet, the patient became cyanotic and then suffered a complete respiratory arrest. Artificial respiration was administered with a bag and mask, but the patient's thorax did not move. About 3 minutes later, reintubation was attempted 3 times without success. The glottis, which could be visualized, was bluish and swollen. Cardiac arrest occurred and external massage was started immediately. An emergency tracheotomy was performed.[1] Ventilation was begun and the standard cardiopulmonary resuscitation measures were applied, but without success.

A postmortem direct laryngoscopy revealed a fragment of the patient's dentures hooked and firmly lodged in the larynx beyond the vocal cords (figure). Apparently, it had been lying somewhere in the pharynx since the day of accident and (after over 13 days of tracheal intubation and more than 5 hours following extubation) was aspirated

during the last oral toilet, blocking the upper airway completely.[2] However, it was removed with a Magill forceps.

This case report emphasizes the importance of carefully examining dentures for evidence of fragments that may be left behind in the upper airway.

Hypercapnia During Cyclopropane Anesthesia: A Case Report

STEPHEN T. BARASCH, MD*
SANDRA BOOTH, CRNA†
JEROME H. MODELL, MD‡
Gainesville, Florida§

CYCLOPROPANE usually is administered by a closed-circle system which relies entirely on chemical CO_2 absorption to avoid hypercapnia. A properly functioning anesthesia machine and breathing circle are essential with this anesthetic technic. A case report of hypercapnia caused by defective equipment during closed-circle cyclopropane anesthesia is described and methods of avoiding this complication are suggested.

A healthy 21-year-old woman scheduled for vaginal hysterectomy was premedicated with pentobarbital (100 mg), meperidine (25 mg), and atropine (0.4 mg) IM. After 45 minutes, anesthesia was induced with thiopental (50 mg) IV and 50% cyclopropane in O_2, administered by face mask via a closed-circle absorber system (total flow 0.5 L/min). The concentration of cyclopropane gradually was reduced to 15%. Approximately 10 minutes after induction, multifocal ventricular premature contractions were noted. Lidocaine (50 mg) was given IV with no apparent effect. About 5 minutes later, the patient appeared to be hyperventilating, with very deep respirations. Her pupils were dilated and skin appeared mottled. Blood drawn from the radial artery showed a pH of 7, $Paco_2$ of 108 torr, and Pao_2 of 320 torr.

Cyclopropane was discontinued and N_2O-O_2 (3:2 L/min) was passed into the circle system. The patient's color improved and her respirations became less labored. Blood drawn 15 minutes later showed a pH of 7.34, $Paco_2$ of 37 torr, and Pao_2 of 230 torr. Ventricular arrhythmias ceased shortly after increasing the fresh gas flow rate to the circle system, and the surgical procedure was completed without further incident. The patient's systolic blood pressure ranged from 110 to 130 torr and her pulse from 90 to 110/min throughout the procedure. She was taken to the recovery room in good condition and had an uneventful postoperative course. The anesthesia machine was removed from the operating room and tested.

Equipment Test.—To assess the efficacy with which the circle system absorbed CO_2, we evaluated ventilatory responses of a volunteer subject. A Godart capnograph was placed just distal to the inspiratory valve and a pneumotachygraph was connected in series with the expiratory hose at the mask Y connector. The expiratory flow was analyzed electronically on a Model M300 Respiratory Parameter Monitor,* to give instantaneous values for minute volume ($\dot{V}_E$), respiratory rate in breaths per minute (f),

f	18	19	23	26	20	17	17
F_{ICO_2}	0	0.05	0.06	0.08	0.05	0.04	0.03

and tidal volume (Vt). The capnograph permitted continuous monitoring of the CO_2 concentration of inspired gas (F_{ICO_2}).

The soda lime was confirmed to be white and the canister bypass valve of the Ohio Model 21 absorber† to be closed fully. We administered O_2 by face mask via the closed system, continuously recording $\dot{V}_E$, Vt, f, and F_{ICO_2}. After 15 minutes, the breathing circle was changed to a semiclosed system by opening the pop-off valve and increasing the O_2 flow rate to 5 L/min. The test was continued for an additional 15 minutes. Results are shown in the table.

Since the failure of the anesthesia machine to absorb CO_2 had been confirmed, we dismantled the breathing-circle components to search for the cause. The canister bypass valve was closed and functional and inspiratory and expiratory valves were in good working order. The soda-lime granules were white, cool, and adherent, forming a solid cake.

Granules from the cake, tested on a blood-gas machine for CO_2 absorbing capacity by placing them in a column through which was flowed a mixture of 10% CO_2 and 90% N_2, gave a P_{CO_2} of 72 torr inflowing and 68 torr effluent, indicating almost no CO_2 absorption. The granules remained white and cool during the 12-minute test period. As a control, fresh indicator soda lime, tested in an identical manner, showed an inflow P_{CO_2} of 72 torr and an effluent P_{CO_2} of less than 10 torr (the lower limit of the blood-gas machine). These granules turned blue within 2 minutes and the column felt warm. Water condensed on the column wall. An additional sample of granules from the absorber was analyzed by a manufacturer‡ of indicator-grade soda lime and was found to have "no indicating qualities."

DISCUSSION

Our practice has been to replace the upper CO_2 absorption canister with the lower canister when the upper attains a stable blue color, and to place fresh soda lime in the lower section. In proposing the use of the double canister, Elam[1] stated that "cycling of the two chambers of absorbent insures complete removal of carbon dioxide . . ." and suggested that the chambers be cycled after 8 hours of rebreathing in a closed-circle system. However, since significant CO_2 leakage through the canister can occur in 5.5 hours if the absorbent is packed incorrectly and peripheral channeling results,[2] time of use *per se* is an unreliable indicator of CO_2 removal.

While recognizing the value of indicator dye in the double canister system, Adriani[3] stressed that measuring the CO_2 concentration of gas after canister use is the only reliable method to judge the completeness of CO_2 absorption.

We have shown that the complete absence of blue color in soda lime assumed to contain ethyl-violet indicator does not insure that the soda lime is capable of CO_2 absorption. Furthermore, since soda lime is manufactured both with and without indicator, it is possible that soda lime without indicator may inadvertently be used. Nevertheless, we were able to detect soda-lime exhaustion by analysis of CO_2 concentration of gas within the inspiratory hose of the circle system.

We do not know when the soda lime was last changed in our machine; however, other patients were anesthetized previously without apparent difficulty. In those patients, however, a semiclosed technic with 5 L/min flows was used; thus, there was little dependence on the absorption canister for CO_2 removal.[4] It was not until we used a closed-circle system (0.5 L/min inflow rate) that the problem was apparent.

In the clinical situation in which incomplete CO_2 absorption is suspected, it is a simple procedure to withdraw a sample of gas from the inspiratory hose and determine the P_{CO_2} with either a CO_2 electrode or an infrared CO_2 analyzer. This maneuver would have been helpful in detecting our problem earlier.

Calibration of the Narkotest® Gas Monitor for Isoflurane

JOSE L. VELAZQUEZ, MD*
ALFRED FEINGOLD, MS, MD†
Miami, Florida‡

THE Narkotest®§ anesthetic gas analyzer was introduced as a simple, inexpensive device to measure in-circuit halothane concentration.[1] It was later shown to respond to all inhalation anesthetics approximately in proportion to the minimum alveolar concentration (MAC).[2] It consists of 4 strips of silicon rubber connected by a lever to a scale pointer. When exposed to anesthetic agents, the strips relax, causing movement of the pointer. This instrument was shown by Lowe and Hagler[2] to respond linearly to 6 inhalation anesthetics.

We have calibrated the Narkotest for the new anesthetic, isoflurane, and summarized the calibration factors for 9 other anesthetics.

Using an O_2 flow of 5 L/min, selected concentrations of isoflurane up to 3% were equilibrated with the Narkotest monitor. Gas concentrations were measured by a Hewlett-Packard gas chromatograph, using appropriate standards, and were plotted against the reading on the Narkotest. The least squares method was used to determine the best fit line through these points.

The Narkotest response to isoflurane is rectilinear ($r=0.99$). As the slope of the line (calibration factor) is 1.8, the Narkotest reading should be multiplied by 1.8 to obtain the isoflurane concentration in volumes percent. The calibration factors for other anesthetics are summarized in the table (third column).

This calibration factor is proportional to anesthetic rubber/gas and oil/gas solubility and inversely proportional to silicon-rubber retention times.[2] Therefore, more potent anesthetics require lower gas concentration to cause the same deflection of the pointer. Since anesthetic potency is correlated with oil/gas solubility, the Narkotest monitor roughly approximates the "MAC meter" suggested by Lowe.[2] When the Narkotest

We Salute . . .

Paul Rudolph Dumke, M.D.

OUR nominee for this traditional "Salute" offers a synthesis of the better attributes of the many thus honored over the years. A portrait of Paul Rudolph Dumke imparts the characteristics of a proud Prussian-Germanic heritage and the area of our country in which he was reared—that romantic and culturally rich region known as The Western Reserve—carved out of the old Northwest Territory. Born in 1911, the only child of Richard Rudolph and Martha Schmidt, young Paul had a strict Lutheran upbringing, progressing through the public school system, where his versatility in learning, leadership, and athletics was ever apparent.

Matriculation at Oberlin on a merit scholarship witnessed the beginning of a series of encounters with wise preceptors who would leave a lasting impress on the student's mind. One would have had Paul concentrate on Germanic studies, another offered the lure of chemistry.

And so it came to pass in 1937, at Western Reserve University Medical School, where certain workers in the vineyard of hypertension, such as Harry Goldblatt and Joseph Hayman, were attracted by the qualities of their student, Dumke. Through their guidance, his path led to the University of Pennsylvania, to the Departments of Pharmacology and Physiology and the inspiration of the inventive minds of Carl R. Schmidt, Grayson McCouch, and Julius H. Comroe, Jr. More than a few publications on respiration and circulation bear the name of Dumke et al.

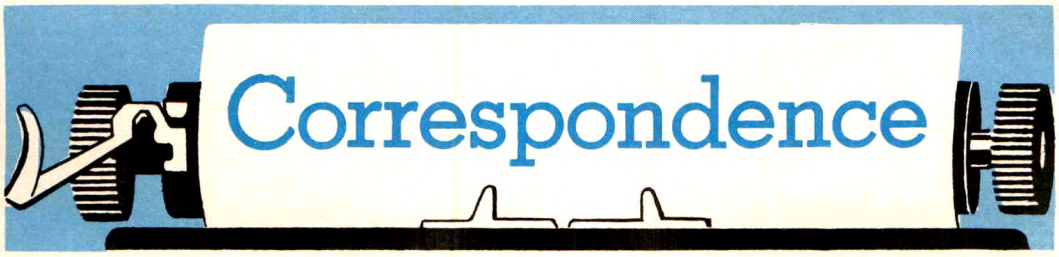
But, time out in 1937 for a felicitous union with Dorothy Louise Foster, and subsequent issue: Robert, now a teacher in the Detroit school system; and Catherine, a paralegal assistant in a Detroit firm. Early on, the family moved from town to town in line of military duty. Those who know the man would not be surprised to learn that medical soldier Dumke terminated a career in the Reserves with the rank of Lieutenant Colonel. Likewise, how logical it was that he should soon join the burgeoning army of anesthetists.

At the University of Pennsylvania in the "forties and fifties." Dr. Dumke earned a reputation as superb clinician, pacifier of surgeons such as I. S. Ravdin, and stern but

sympathetic teacher of beginners. As it is the mission of an academic department to disseminate wisdom, Paul Dumke, by now a professor, was the first to desert the ranks of Dripps, Lamont, Eckenhoff, and Vandam, for the post of Chief at the Henry Ford Hospital in Detroit, in 1953. While building an exemplary program there, time was sequestered for organizational work: Director of the ASA; Governor of the College; Chairman of the AMA Section on Anesthesiology; and Trustee of the IARS.

You would have to say of Paul Dumke's other pursuits that in general he relishes every facet of living: gourmanderie, quaffing, the aroma of fine tobacco, piscation, gunning, bidding the grand slam, and savouring the printed word. On principle, he religiously shuns exercise but keeps a poodle on leash. A recent tribute by cohorts of the IARS depicts Paul Dumke as a dear and true industrious friend—strong, constant, pleasant, and wise!

NITROUS OXIDE AND CARDIAC PAIN. A double blind study in 69 patients with chest pain following acute myocardial infarction compared 35% nitrous oxygen with 100% oxygen as an analgesic. Both drugs were inhaled for 5 minutes. Nitrous oxide had a beneficial effect in 74% of the episodes of pain and produced complete pain relief in 39%. In contrast, oxygen produced partial relief in 29% and complete relief in none. Blood pressure and heart rate did not change significantly during nitrous oxide inhalation. There was no evidence of bone marrow depression in 3 patients who had inhalations lasting a week. Nitrous oxide offers an alternative to narcotics for mild cardiac pain and a useful adjunct to narcotics for severe pain. *(Thompson PL, Lown B: Nitrous oxide as an analgesic in acute myocardial infarction. JAMA 235: 924-927, 1976)*



To the Editor:

The effects of ketamine (Ketalar®, Ketaject®) on the EEG in normal adult subjects and in epileptic patients are controversial. Some authors[1] have found no evidence that ketamine induces seizure discharges in epileptics or normals, while others[2-4] warn of the drug's potential epileptogenicity. We recently completed a study[5] on this subject that may be of interest to anesthesiologists.

In our study of ketamine in 26 patients (16 men, 10 women, ages 17 to 58 [mean 31.3 years]) with an unequivocal history of either focal or generalized epilepsy, the effects of ketamine (1.5 to 2 mg/kg) were measured with serial EEGs for each patient while awake with hyperventilation and photic stimulation, while asleep after 18 to 24 hours of sleep deprivation, and during and after IV injection of ketamine.

After administration of ketamine, all patients developed a catatonic state, which was dose related in duration. Twenty-two patients hypoventilated and/or had respiratory dysrhythmia with brief episodes of apnea; 5 had longer episodes of apnea requiring brief supportive ventilation.

Characteristic EEG changes appearing during ketamine anesthesia consisted of generalized high-amplitude synchronous beta waves, often in association with generalized theta waves of 4 to 5 cps. Quasiperiodic delta complexes every 2 to 6 seconds, having amplitudes of up to 400 microvolts, were seen in 9 patients.

Several behavior changes apparently induced by ketamine were observed. Unusual postures were exhibited by 12 subjects, distorted perceptions by 25, motor hyperactivity by 5, and sporadic myoclonic jerks by 1 patient suffering from psychomotor seizures. No patients developed seizures. There was a striking dissociation between EEG changes and behavior. The same EEG features of theta and synchronous beta activity were seen during the catatonic and recovery stages. Furthermore, no behavior differences could be noted between periods with quasiperiodic delta and periods with generalized theta activity.

To be sure that EEG and behavior changes under ketamine anesthesia were not just coincidental, we compared them with observations made during physiologic awake and asleep states, using the following criteria: Type 1 activation was defined as the occurrence of epileptic discharges (ED) in the tracing following the testing procedure when no such abnormality was present in the awake tracing. Type 2 activation was defined as an increase of 30% or more in the frequency of ED following the activating procedure when such discharges were already present in the awake record. ED was defined as spikes and/or spike and wave complexes, either focal or generalized.

Nine patients had normal awake tracings; in 2, type-1 activation occurred both during sleep and during ketamine anesthesia. Seventeen patients exhibited type-2 activation, 12 during sleep and 6 during ketamine anesthesia. In 15 patients, ED was either precipitated or aggravated by spontaneous sleep, while ED followed ketamine anesthesia in 8 awake patients. Ketamine appeared less apt to activate temporal-lobe ED than generalized ED. Two of the 12 patients with temporal-lobe seizures had a decrease or complete suppression of ED during ketamine anesthesia. In this study ketamine did not display epileptogenic activity.

Our findings[5] are certainly consistent with those of Corssen's group[1] and contradict those reported by Ferrer-Allado[2] and by Bennett and associates[3] and the implications of Winters,[4] all of whom suggest that ketamine may precipitate or aggravate seizures in the epileptic patient. One point might be re-emphasized, namely, that when epileptic patients are studied, any seizures that occur in the experimental condition may be coincidental. In our study, we compared EEG activity in these patients both under ketamine anesthesia and under normal waking and sleep-deprived sleeping states. Under these controlled conditions, we found that, with ketamine, abnormal EEG activity or aggravation was certainly no more common than under the other conditions and perhaps even less so.

* * * * *

To the Editor:

Thank you for giving me an opportunity to answer Dr. Celesia's letter regarding the use of ketamine for epileptic patients. The uniqueness of ketamine's CNS action has led to enormous controversy, opinions ranging from its being the anesthetic of choice[1] to being totally contraindicated[2] in patients with seizure disorders. These controversies result from differences in parameters investigated, differences in experimental models, and differences in EEG interpretation.

Although measuring activation or depression of the CNS by measuring neuronal activity of the brain cells in various parts of the brain is impossible in humans, neuronal activity by measurement of multiple unit activity (MUA) has been measured in animals[3] and in the thalamic area of man[4] before and after administration of anesthetic agents. Winters and associates[3] have reported that, in animals, the MUA in the reticular activating system may be stimulated, with the behavioral appearance of sleep, when EEG waves are similar to those in a state of alertness (low-amplitude fast waves). An example of this is during REM or paradoxical sleep. Dr. Winters also reported that MUA or neuronal activity is stimulated during occurrence of epileptiform discharges in limbic and thalamic regions, while the animal appeared immobile or catatonic after ketamine administration. Therefore, to say whether an anesthetic agent would depress seizure discharges, depression of neuronal activity should be correlated simultaneously with behavior and EEG.

Dr. Celesia studied the cortical EEG in epileptic patients. In our study,[5] we measured, in addition to the cortical EEG, limbic and thalamic EEGs. This did not necessarily correlate with cortical EEG changes. Only when the epileptiform discharges spread to the cortical region did the patient manifest seizure activity. While limbic and thalamic seizure discharges were occurring, patients manifested similar behavior to that reported by Dr. Celesia, such as motor hyperactivity sporadic myoclonic jerks, and unusual postures.

However, the difference between Dr. Celesia's study and ours was in the concomitant measurement of limbic and thalamic EEG, which demonstrated electrical seizure activity during these behavioral manifestations despite a nonsignificant cortical EEG. It is possible

that Dr. Celesia's patients were indeed having limbic and thalamic seizures but that this was not evident on the cortical EEG being measured.

We have also found that the origin of seizure discharge did not necessarily start from the established seizure foci of the individual patient, which means that the existence of seizure foci is not necessary for ketamine to induce seizure discharges. This could explain the isolated reports of normal, seizure-free, patients having seizures after ketamine administration.[6]

In our initial work in unrestricted animals,[3] which had cortical depth EEG electrodes and MUA measurement in the reticular activating system, we found that the MUA following ketamine was higher than control awake, sleep, and REM or paradoxical levels, which further substantiates that ketamine is not a depressant but a stimulant of the CNS.

In Dr. Celesia's initial experiment in animals,[7] although cortical and depth EEG was measured, MUA was not, yet the EEG changes he saw were similar to those in our study. The animals in Dr. Celesia's study were restricted and also given other drugs such as ether, gallamine, and local anesthetics. In our study, the animals were unrestricted and measurements were continuous for several days before ketamine administration, and MUA was measured continuously for 24 to 48 hours up to 7 days after ketamine. No other drugs were given concomitantly.

If ketamine suppresses epileptic discharges, one has to show that ketamine depresses MUA, which is usually increased during a seizure, and not rely only on behavior and the EEG. Dr. Celesia did not measure neuronal activity in both animals and man, mainly relying on behavior and cortical EEG, which does not necessarily correlate with neuronal activity of depth electrode EEG. To convince one that ketamine is indicated for epileptic patients, ketamine should be shown, by MUA measurement, to depress neuronal activity and that correlative existing seizure activity is terminated by ketamine. The ideal study would be to observe the effect of ketamine on neuronal activity in the human brain. Although we have studied such activity in the thalamic area in man with N_2O and thiopental, we are yet to study ketamine. However, our initial results with N_2O and thiopental correlate with those of Dr. Winters.

To the Editor:

Thank you for the opportunity to comment on the use of ketamine in epileptic patients. Proposals that there is no relationship between EEG burst discharge activity and ketamine may be doing a disservice to patients with abnormal EEGs.

Our published EEG study[1] did not give some of the primary clinical data one needs for a discussion of clinical relevance. Many authors have reported high-voltage delta-wave activity[2] after onset of the low-voltage, rapid-frequency theta-wave discharge. We also illustrated focal spike and wave discharges; these were not "coincidental." Indeed, we used care to eliminate coincidence as much as possible.

We studied our patients over a 3-year period in a special seizure-observation unit. A careful record was kept of seizure frequency and type for 3 months prior to entry in the study. Blood levels of seizure-control medications were taken periodically to assure that absorption was constant and predictable. EEG studies, repeated twice, included sleep and photic stimulation, using the 12 to 20 International System with 17 scalp silver-silver chloride and 2 ear leads. The EMG was also recorded.

For the test period, we did split-image videotape recording to get real-time correlation between motor activity and EEG electrical activity. Since our initially reported study, we have repeated the same study in the experimental group with thiopental and halothane. We have also set up an experimental lesion in the rhesus monkey using a penicillin-induced focal cortical lesion. Thus we carefully excluded coincidental seizure activity and demonstrated a significantly different response of ketamine in comparison with other anesthetic agents. Twenty minutes of continuous baseline tracings certainly gave us ample background data. I should point out, however, that our patients were all children, including two without a seizure history, studied because their "random movements" clinically resembled major motor seizures.

Abnormal EEG rhythms were induced in all patients by ketamine. Motor manifestations were variable, extending from rigidity, predominantly unilateral and periodic, to unilateral clonic-tonic adversive seizures. Tonic-clonic activity was also seen in the two "normal" children, as were polyspike and wave discharges. In the epileptic patients, the EEGs differed from their usual pattern, frequently demonstrating suppression of their usual focus, with subsequent appearance of a mirror-image type focus in the opposite hemisphere. Studies in monkeys uniformally demonstrated this mirror-focus activity on implanted electrodes, as well as burst discharge in subcortical areas which did not always transmit to the cortical electrodes.

The time between administration and onset of seizure activity was variable, IM administration having a more delayed onset. In 1 patient, only IV administration elicited the EEG abnormality. We assume this relates to uptake but did not do blood levels. Onset with the IV route was usually 60 seconds. The duration of change was also variable, 1 patient showing a post-test change in need for antiepileptic drugs. In a second series of 10 patients studied after the initial group, seizure was frequently greater in the recovery period.

Thiopental and halothane studies gave entirely different results, motor activity being suppressed in all. Several had activation of their primary focus by thiopental but no change in electrical activity. Halothane at MAC 1 concentration suppressed the abnormal electrical activity, with reappearance in the recovery period. Thiopental dosage was that necessary to suppress the lid reflex.

It was the conclusion of the pediatric neurologist and the electroencephalographer that there was definitely a relationship between ketamine and epileptiform seizure pattern occurrence. We have now extended the study to a larger group.

If we believe that seizure activation is undesirable in epileptic children, we are led to the conclusion that ketamine is not the ideal anesthetic for such patients. We are aware that the drug is used frequently in neurophysiologic studies. Prior reports[3] of this use, interestingly, include a much higher incidence of rigidity, posturing, excessive secretions, and airway problems. We would wonder what EEG monitoring would demonstrate in these patients.

As for coincidence, these studies were carefully supervised and monitored by our Department of Neurology, and the electroencephalogist reviewed the tracings later off line to rule out bias. The right temporal spike and wave discharges illustrated in one case

occurred after 2 separate injections, once 17½ minutes later and once 21½ minutes later. This patient's baseline EEGs had never before demonstrated right temporal spike and wave discharges. Coincidence? I think not.

To the Editor:

My first impulse after receiving your request for an answer to Dr. Celesia's letter was to pass this round, having previously presented an editorial[1] and a discussion[2] on this topic. However, since the controversy regarding the relationship of ketamine to epilepsy seems endless, I decided to make one more attempt at stating my views. In reviewing the controversial reports pro[3-10] and con,[11-13] several pertinent points appear to be confused.

1. Epilepsy is not one state but a series of syndromes encompassing:
   a. Abnormal EEG activity, or
   b. Abnormal EEG activity associated with some motor response, such as ear twitching, or
   c. "b" plus gross motor and electrical discharges.

2. The EEG patterns induced by ketamine in animals and man are—in my opinion—epileptogenic; that is, the midbrain, diencephalic, and cortical hypersynchronous 1 to 4 Hz EEG slow waves of high amplitude, alone or intermixed with spike bursts, represent epileptic brain-wave activity.[3,7] Even the EEG patterns which we describe during stages II-A and II-B anesthesia are epileptogenic.[7] The intermittent appearance of high-amplitude, high-frequency seizure discharges in the limbic lobe during ketamine-induced cataleptic anesthesia (stage II-C) is sometimes associated with facial or hind-limb twitching.[3,7] Limbic seizures of this type are often reported to be characterized by bizarre, inappropriate, and cataleptoid behavior in man.

3. Grand mal seizures were not often noted following high doses of ketamine. However, the parent agent, phencyclidine, induces a similar progression of actions. During phencyclidine-induced cataleptic anesthesia, limbic seizures with hind-limb twitches were also noted.[10] Doses of phencyclidine slightly higher than those necessary to induce cataleptic anesthesia induce the same progression, followed by generalized grand mal seizures (fig 11).[10]

4. Epileptics manifest a variety of subcategories of signs, symptoms, and etiologies. The fact that some investigators demonstrated that ketamine increased epileptic activity,[1-10] and others an inhibition,[11-13] implies variations in experimental design, such as varying degrees of antiepileptic pretreatment or a variance in the subcategory of the epilepsy studied. Thus, epilepsy can not be discussed in simplistic terms. Diphenylhydantoin is not effective against all forms of epilepsy. Even patients who respond to this agent may exacerbate the epileptic syndrome following significant elevation of the dosage. Some epileptics have asymptomatic periods. In addition, antiepileptic agents appear to be more effective at some periods than at others. Thus epilepsy is time, drug,

and dose dependent. Ketamine may improve some epileptics, make some worse, and have no effect on others.

5. Dr. Celesia claims to have observed a striking dissociation between EEG and behavior. He warns against excessive or exclusive reliance on the EEG to understand the nature of ketamine anesthesia. He offers no better criterion and leaves us with a sense of a "supernatural" action of ketamine. Most paradoxical situations in neuropharmacology in which behavior and EEG do not seem to be clear-cut eventually resolve themselves. They are usually an indication of our lack of sufficient knowledge to make the correlation. To imply categorically that there is no correlation between behavior and EEG is absurd.

6. Dr. Celesia[12] further asserts that we[7] write: "The anesthetic state induced by ketamine is due to 'limbic seizures.' " We make no such statement. Where he conjured up this statement is not clear, but what is clear is that he did not read our paper carefully. We state that during cataleptic anesthesia, limbic seizures may occur. In our figure 9, demonstrating the EEG during the catatonic state, the limbic seizure appears at 5 minutes but not at 30 minutes. In our Methods section, we describe the gross behavior, EEG, and multiple unit activities necessary for the cataleptic state of anesthesia; limbic seizures are not mentioned.

7. In the discussion of Dr. Corssen's paper,[11] Dr. Domino states: "It is not good medical practice to slander a drug without thorough proof." We believe that scientific investigations should be designed to elicit the truth regarding the nature of a drug action irrespective of its clinical reputation. It is our hope that Dr. Domino did not really wish his statement to read as it does. As was pointed out by Schettini[2] and my subsequent discussion of his paper, if one is aware of the pharmacologic actions of a drug, it may be combined with appropriate agents to block the potentially dangerous actions and augment the more desirable effects; antiparkinson therapy with phenothiazines is an example of this. Thus, I regard our search for an understanding of the properties of drugs such as ketamine to be necessary for improved patient care.

8. It must be reiterated that, as an anesthesiologist, you must make the final decision on the utility of each agent you use. Please read the pertinent papers regarding this controversy and decide for yourself the place that ketamine and drugs of this type have in your anesthetic routine, especially in the epileptic or neurosurgical patient. By being aware and concerned with anesthetic problems such as these, the body of anesthesia knowledge will widen, anesthesiologists' skills will broaden, and patient care will improve.

To the Editor:

Dr. Eli Brown's article on the single-needle lateral approach for lumbar sympathetic block[1] alludes to the lack of previous descriptions of this technic in the literature.

We described this technic in ASA Annual Refresher Courses in 1973, 1974, and 1975, as well as in *Refresher Courses in Anesthesiology,* volume 3, 1975 and *Advances in Neurology,* volume 4, 1974.

The major advantage of the lateral approach at L-2 as described above is the use of smaller quantities of local anesthetic or neurolytic agents. Since the preganglionic outflow from the cord to the sympathetic chain ends at L-2, there is no need to produce block below that level. As the sympathetic chain lies in what is only a potential fascial plane, this plane is distended by the local anesthetic introduced. There is no evidence to indicate that table tilting is necessary to involve adjacent segments. We have demonstrated this fact radiographically in the cervical region in our article on stellate ganglion block.[2]

Using a distance of 10 cm rather than 12½ cm from the midline as the needle point of entrance, we have been able to avoid puncture of the kidney, a complication suggested by Dr. Brown. In a large series of patients, we have had no renal complications. Problems with this technic have been related only to improper needle placement, which are obviated by radiographic control.

To the Editor:

I want to thank Dr. Carron for directing me to the sources listed in his Letter to the Editor. Although I was unable to find a description of the technic for a lateral approach to sympathetic block at L-2 in either *Advances in Neurology* or *ASA Refresher Courses in Anesthesiology,* volumes I and II, I did find an excellent description of the procedure used by Dr. Carron in *ASA Refresher Courses in Anesthesiology,* volume III, 1975. Unfortunately, this publication was not available to us until after our article was prepared for publication.

In any event, I do not understand how Dr. Carron can be certain that he does not inadvertently puncture the kidney, particularly in view of the proximity of that organ to the path of his needle, and our experience with cadavers. I honestly do not know whether or not inadvertent puncture of the kidney is harmful, but it seems to me that one should avoid it by performing the block at a lower level. Even though our technic requires

a larger volume of solution, I think Dr. Carron would agree that the use of 20 ml of 1% lidocaine or 0.25% bupivacaine is not excessive.

To the Editor:

I would like to make some additional comments regarding the "Single-Needle Lateral Approach for Lumbar Sympathetic Block" by Brown and Kunjappan.

We have used a slightly different technic of lateral approach, also using a single needle for temporary blocks with local anesthetics, and a double-needle technic for permanent sympathectomies using 6% aqueous phenol.

We place the patient in the lateral position with the side to be blocked upward. A 6-inch needle is inserted between the rib cage and iliac crest, about 12 to 13 cm from the posterior midline, and aimed at a 35 to 40 degree angle toward the anterior surface of the vertebral body. After impinging on the vertebral body, the needle is walked off, until it is just anterior to the body, and the medication is injected.

For blocks using local anesthetics, no x-rays are taken. For permanent sympathectomies with 6% aqueous phenol, we have found better results and longer-lasting blocks by using 2 needles through a single skin wheal by the lateral approach. One needle is pointed upward and the 2nd needle downward, so that they impinge on the bodies of L-2 and L-4 or L-3 and L-5. X-rays are always taken (PA and laterals) to confirm their position, and 4 ml of 6% aqueous phenol is injected at each level.

The procedure is not usually painful, except when the needle hits the periosteum of the vertebral bodies. A small amount of local anesthetic usually eliminates this pain.

We have done over 500 phenol sympathectomies, using the described technic, over the past 10 years, with 2 serious complications: retroperitoneal hemorrhages, which required only conservative management. Other, more common complications, have been backache, lasting a few days, and inguinal burning and paresthesias, lasting a few days to a few weeks. The latter occur in about 10 to 15% of the patients.

Since we often do these blocks on very-poor-risk patients, with far-advanced disease, a number of patients have died from their underlying heart disease, or have lost limbs which did not improve with the sympathectomy. In no patient could this be directly related to the sympathetic block.

The so-called "steal syndrome," where deep circulation gets worse at the expense of superficial warming and improved color in the sympathectomized limb, has not happened in our experience.

To the Editor:

I enjoyed reading Dr. Brown's article, "Single Needle Lateral Approach for Lumbar Sympathetic Block." His method is indeed simpler and more comfortable to the patient than the classic approach. But it is not original. Besides Lewis' sketchy technic mentioned by Dr. Brown, there exist at least 3 lateral, 1-or-2 needle, approaches.[1-3]

Reid and Shumacker point out the advantages cited by Dr. Brown (accuracy, simplicity, comfort to the patient), and the spread of the solution along the whole lumbar sympathetic chain. Reid places 2 needles 10 to 12 cm laterally to the spines of L-3 and L-4 and directs them to clear the anterolateral border of the vertebral bodies. Even only 6 ml of phenol suffice to block the lumbar chain.

Shumacker inserts 1 needle 10 cm off the spine of L-2 at a 30° angle toward the median sagittal plane and directs it to clear the anterolateral margin of the vertebral body and to place its tip in front of the psoas muscle. He finds that 10-ml volumes extend from L-1 through L-3. I have used Shumacker's technic and appreciated its advantages for the past 10 years. If one attaches a syringe filled with a few ml of air and solution to the needle, he can feel the "loss of resistance" as the needle tip leaves the psoas muscle, when it is correctly placed.

Löfström inserts 1 needle (at L-2) or 2 needles (at L-2 and L-4), 7 to 10 cm off the midline. However, he first aims at the transverse process, as in the classic methods. He blocks the lumbar chain with 1 injection of 15 ml.

The proximity of the kidney may be a disadvantage to the L-2 route. However, Shumacker's diagram and my experience suggest that if one carefully observes his landmarks, the needle only pierces the muscular mass (sacrospinalis, quadratus lumborum, and psoas) and remains medial to the kidney. Dr. Brown's excellent paper should encourage anesthesiologists to try this valuable approach.

Ray J. Defalque, MD

* * * * *

To the Editor:

Dr. Defalque correctly points out that a number of lateral approaches have been described for lumbar sympathetic block. All of them, however, are either performed at the level of L-2 or involve more than a single needle. Of greater interest, however, is the fact that Dr. Reid states, "Puncture of the kidney sometimes occurs and is recognized by a pendulum swing of the needle or by the escape of urine through the needle. The presence of peri-ureteric fibrosis at subsequent ganglionectomy has occasionally been seen and it is possible that urinary symptoms may occur owing to ureteric damage." He does go on to say that in most cases the symptoms are transient and full recovery results. But the point is, that damage to the kidney is certainly possible if one uses a wide lateral approach at either L-2 or L-3.[1] The lateral approach described by us at L-4 precludes the possibility of damage to the kidney while still providing effective blockade of the lumbar sympathetic chain.

To the Editor:

I read with interest the article on the single-needle lateral approach for lumbar sympathetic block by Drs. Brown and Kunjappan. Dr. Donald P. Todd and I have frequently performed single-shot and continuous-catheter lumbar paravertebral sympathetic block for reflex sympathetic dystrophy of the lower extremities. Our technic involves the taking of a scout PA x-ray film of the lumbar spine with an 18-gauge needle positioned on the skin at the upper edge of the 2nd lumbar spinous process. After identifying the proper level, the skin is prepared with an antiseptic solution and draped in a sterile manner. A skin wheal is raised 5 to 6 cm lateral to the upper edge of the spinous process of the 2nd lumbar vertebra.

A 20-gauge, 12.5-cm needle is then placed through the skin wheal and contact made with the transverse process of the 2nd lumbar vertebra. The marker on the needle is set a distance of 3 to 4 cm from the skin surface before redirecting the needle medially and cephalad so that it slides off the upper border of the transverse process and the lateral aspect of the vertebral body. By sliding off the upper border of the transverse process, painful paresthesias to the lateral thigh (L-2) are avoided. The position of the needle is verified by PA and lateral x-ray films before injection of 20 ml of anesthetic solution.

Similarly, multiple encounters with the periosteum and blockade of the 2nd lumbar somatic nerve should not be a problem. Multiple periosteal contacts can be considerably reduced by taking an initial scout x-ray film and accurately locating the site of needle insertion. Also, the hypalgesia in the area of the 2nd lumbar dermatome seldom interferes with the diagnostic or therapeutic values of the block.

By following the classic approach, we have not found it necessary to use the wide lateral approach for lumbar sympathetic blockade. A single needle with its point at the anterolateral aspect of the 2nd lumbar vertebra is sufficient to precisely and reliably block the lumbar paravertebral sympathetic chain.

Department of Anesthesia
Massachusetts General Hospital
Boston, Massachusetts

In each issue of the Journal an article of particular interest and value to anesthesiologists, which has been published elsewhere, will be presented. Primarily the material will contain fundamental basic information which has been presented by anesthesiologists, physiologists, pharmacologists, and others and, on occasion, by commercial firms. In the last instance, these reprintings are not to be construed as an endorsement of the particular commercial firm or its product by Anesthesia and Analgesia—Current Researches.

Fundamental Principles for Preparing Psychology Journal Articles*

HARRY F. HARLOW†
University of Wisconsin

As retiring Editor of the *Journal of Comparative and Physiological Psychology*, I feel that I have one remaining responsibility to my psychological colleagues. Having passed judgment on about 2,500 original manuscripts and almost as many revisions in my 12 years as Editor, I believe I should bequeath to posterity some principles of scientific reporting that I have formulated only through countless hours of moonlighting.

COVERING LETTER

In plotting the publication of a manuscript the prospective author should think first about the covering letter. It is an unforgivable error to write, "I am submitting a manuscript for your consideration. . . ." This evasive method gets you nowhere with editors. Even if the nondirective technique works with many patients, there are some sick people who are best approached using positive measures.

There are a number of general principles underlying a good covering letter, and they can be illustrated by example. I offer the following:

DEAR HARRY:

I am submitting the manuscript, "Creative Thinking by Paramecia," for publication in JCPP. My chairman has assured me that upon acceptance of this manuscript he will recommend me for promotion to associate professor. Two recipients of the Distinguished Psychologist Award have reviewed this paper and recommend it highly.

I am pleased to see that you are one of five candidates for President of the American Psychological Association. As you know, I have nominated you for many years and will probably give you my support in the future.

Because of the unusual significance of these researches, I would like early publication, which I will finance from my National Institute of Mental Health grant.

Warm Regards,

John Hopeful
Assistant Professor

The battle is now half won. You will get a fair shake.

*The publication costs for this report were borne by the American Psychological Association.

†*Still* at the University of Wisconsin.

Copyright 1975 by the American Psychological Association. Reprinted by permission of publisher and author.

INTRODUCTION

Almost all scientific papers include an introduction even though large parts of it are frequently buried in the sections labeled Method and Results. However, the total omission of an introduction constitutes a glaring error, and, anyway, it is fun to write introductions—one is not constrained by facts.

One way to write an introduction is simply to state what the experiment is all about and make predictions about the outcome. Since the data will already have been collected and processed, you will have no difficulty in making insightful predictions. As all famous historians know, one can predict the past with great precision. However, prediction is one of the great booby traps into which young and inexperienced psychologists often fall. All their predictions are confirmed; older men know that this never happens. The proper technique is to select the prediction of minimum import, or throw in a completely extraneous one, and have this prediction fail. Honesty is the best policy.

Although some psychologists write simple, straightforward introductions, this is commonly considered to be *déclassé*. In the sophisticated or "striptease" technique you keep the problem a secret from the reader until the very last paragraph. Indeed, some very sophisticated authors keep the problem a secret forever. Since I am interested in readers as well as authors, I advise that readers always approach introduction sections using the Chinese technique—begin at the end and read backward.

The function of the introduction is to impress your colleagues with your scholarship and erudition—academic appointments are seldom made on the basis of a results section. Scholarly one-upmanship is attained with an unending number of nonspecific references, such as:

"The up-and-down effect was first discovered by (_____, 1762) and this study led to many fruitful investigations (_____, 1804; _____, 1827; _____, 1844; _____, 1861; _____, 1874; _____, 1888; _____, 1894; _____, 1911; _____, 1917; _____, 1928; _____, 1937; _____, 1944; and _____, 1952). Beyond these researches the broad implications of this discovery led to related studies on the in-and-out phenomenon (_____, 1829; _____1855; _____, 1888; _____, 1914; _____, 1927; and _____, 1950), and the around-and-about law (_____, 1884; _____, 1914; __, 1933; _____, 1947; _____, 1952; _____, 1952, and _____, 1960)."

Often, but not often enough, young and lazy authors are frightened away from this technique simply because they are appalled by the amount of work involved in reading the literature, especially if part is written in some foreign language. However, there is no excuse for this attitude; the author should remember that he is not reading the literature—just citing it. Anyway, he can always rely on some scholarly article in *Psychological Bulletin* as a secondary source to provide an impressive reference list with almost no effort.

Occasionally editors object to overly extended, striptease introductions and to long lists of nonspecific references. At this point the author should take the bull by the horns and write the editor a nasty letter accusing him of rigidity, illiteracy, and lack of scholarly interests. Editors are busy and editors are human. They can be broken—don't pamper them.

METHOD

To write a good Method section, one must be an idealist. If this section is to be understood, it must be clear, orderly, and systematic. The best way to achieve this is not to tell what really happened, or if you must tell, wait as long as is physically possible. Your four groups of *Ss* should always add to 20 or 30 each. If 7 *Ss* in Group 2 died of pneumonia and 19 *Ss* in Group 3 were suffocated, don't put it in the Method section. The death of these *Ss* was not planned but resulted, and the information obviously belongs in the Results. There is also good reason for putting this information in the Discussion because you can then mediate on how different the results might have been had the *Ss* lived.

A mechanical problem that often creeps up in Method relates to the spelling and meaning of words such as "maize," "liman," and "maccaccuss resus." Fortunately there is a fundamental rule. Writing manuscripts is a tedious process and time means money. You must protect your time in every possible manner. If you cannot spell or do not know the meaning of a word, don't look it up in *Webster's Third New International Dictionary*. If the word isn't in Thorndike and Barnhart, 95% of your psychological audience won't know the meaning of the word or how to spell it anyway. Moreover, that's the Editor's responsibility. Let well enough alone.

RESULTS

The Results section comes in a very convenient place, and one way to start it is to put the procedures which you inadvertently omitted from the Method section—which you are too lazy to rewrite—at the very beginning of the Results.

If the Editor objects, point out that you are doing this for the sake of continuity. The next problem can only be resolved by reference to the Procedure. Reread the Procedure section and find out the order that you said you were going to follow; then, carefully rearrange that order in the Results. If you write succinctly and clearly, there is a real danger that the reader will only read your manuscript once, and every psychologist worth his salt recognizes the importance of overlearning. Then, too, if he has to struggle to understand it, he will naturally attribute the difficulties to the abstruseness of the problem.

The most important items in the Results will probably be the figures. Authors seldom realize the importance of figures and consequently fail to give them sufficient attention. It is absolutely imperative that the figures be of professional quality. This may cost a little money, but even with academic salaries what they are, the cost is cheap compared with the value of the man-hours spent in gathering and processing the data. The ordinate and abscissa should be boldly drawn and the curves should stand out like sore thumbs, which they frequently really are.

Now we are at the critical point. It is important to make sure that all legends, all numbers on the ordinate and abscissa, and all titles are completely unreadable. If you fail to do this, there is a real danger that editors and readers will compare the information given in the graph with what is written in the Results and Discussion and call the discrepancies to your attention. Fortunately your figures can be made unreadable at a high academic level by following a few simple rules. Draw the figure on paper 2 ft. sq. and never purchase templates with letters more than ¼ in. high. Then when the figures are reduced in size for Journal publication, the data will remain a personal secret. You can subsequently let out the data you are not trying to hide by personal correspondence.

Even authors who follow this rule—and the general principle is widely understood—frequently make a completely unforgivable error by sending glossy prints of their figures to the Editor. If the Editor has already recognized the fact that he has presbyopia and has purchased glasses, he may insist that the graphs be redrawn, and then the jig is up. However, if you send the original drawings and simply scratch out in pencil the copy for the carbon which some editors require, you have a high chance of success. A better technique is to send the carbon without figures. Most editors will relay this carbon to a consulting editor without checking for figures, and a single favorable review frequently insures publication.

Another good technique is to supplement the figures by presenting the data for individual animals in lengthy tables without means, medians, or standard deviations. No reader, and certainly no editor, will ever take the trouble to make the necessary computations to check your curves or statements of significance. The additional advantage is that long, detailed tables carry the implication that you engaged in an overwhelmingly complicated piece of research.

DISCUSSION

Whereas there are firm rules and morals concerning the collection and reporting of data which should be placed in the Results, these rules no longer are in force when one comes to the Discussion. Anything goes—shoot the moon—the sky's the limit!

Even though one is going far afield, the endeavor should not be random, but the deception should be achieved with skill and grace. The most important fundamental guiding principle is to repeat the predictions made in the introduction—elaborating them if possible—and then to describe the importance of your work in broad generic terms and never get down to mundane fact. In Discussion sections one does not discover things about maze performance, minutes to run down a straight alley, 48 hr. of food deprivation, or the number of mechanical puzzle devices opened—one makes breathtaking discoveries about learning, drive reduction, motivation, and curiosity. After all, this is the way psychologists are going to talk when they present and discuss their work at scientific meetings, and no man attains fluency in the jargon without practice.

Very occasionally some psychologist makes the mistake of saying what is worth saying in the Discussion and then stopping. This is interpreted by other psychologists as

indicating that the person lacks verbal skill and creativity. Anyone can talk effectively about data which actually exist.

If your experiment has any merit whatsoever, and little is required, there is the likelihood that someone else will do it later and do it better. To save face it is important to engage in the alibi-in-advance technique. Endless Discussion pages can be consumed by describing how you would do the experiment if you were to do it over, and the joy of this device is that no data need be collected. You have the fellow who is going to be so cold and calculating as to check your results, on the run, and if you are smart enough, no matter what he obtains, it will be a dry run.

Even if you have only completed a single experiment you can greatly augment your data by several pages of description of the results which you would have obtained had you done a long series of related experiments. Furthermore, a clarity is achieved by describing the experiments that were not done instead of those that were because the results in the imaginary experiments come out in an integrated, orderly manner that is seldom achieved in the laboratory. Remember that data collection is a routine process and the brilliant scientist will rise above it when he comes to the Discussion.

Nothing is now left except to find a way to end the Discussion section, which has become so long and so confused that most readers will have forgotten what the original problem was about anyway. Discussions should be concluded in a friendly, charitable, and slightly condescending manner. First, say a few little things about the difficulties of doing research, particularly research in your chosen area. Then point out that there are a few little technical problems and research odds and ends that need to be picked up before your area of choice is completely neat and tidy. Finally, explain that once the research trail has been broken, less strong bodies can follow along.

FOOTNOTES

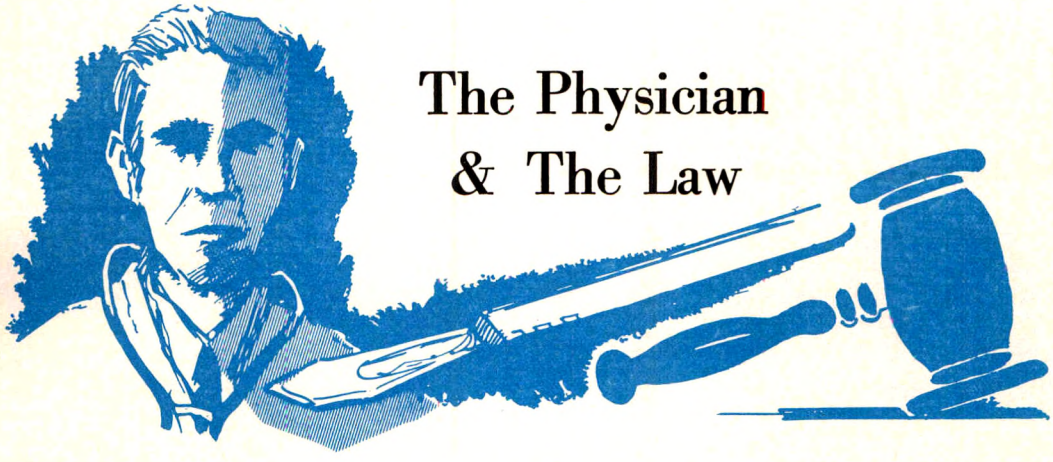
Finally, one comes to the footnotes. Footnotes are always on a separate page (or pages) and there is a chance that the Editor will miss them, particularly if the typewritten material is single-spaced and turned upside down. Thus, here is an opportunity to introduce a couple of additional pages of complete trivia. If the Editor should discover them, nothing will be lost, for paper is cheap. Remember that this is your last chance to get in some padding, and never forget the fact that promotion is the prerogative of deans and final decisions are frequently weighed on other scales than those of justice.

Special attention should be given to one footnote—the acknowledgment. It is this one that separates the men from the boys. Since most experiments are not worth doing and the data obtained are not worth publishing, great care should be taken to protect one's reputation when one's name is associated with the conventional potboiler. This can be achieved by a simple and honest footnote.

"The author (or authors) had very little to do with this research. The idea was stolen from Dr. _____, the experimental design was proposed by my (our) statistical consultant, Dr. _____, the *S*s were run by Mr. _____ and Miss _____, the data were processed by the mathematical computing center, and the paper was completely rewritten by Editor _____, on the basis of extensive notes and suggestions made by Consulting Editor _____, whose name was inadvertently left off the masthead of the *Journal of* _____."

EDITORIAL POLICY

Faced with a mounting flood of uninspired researches and watching publication lag continuously mount despite multiple allotments of additional *Journal* pages, I came to realize that my editorial policies, even though rigid and unreasonable, were incomplete or else in error. For a long time I thought there was no solution, and then I realized I was wrong. I established a new *JCPP* policy and formalized it with a rubber stamp, only to realize that my term as Editor had already expired. But at least I have the rubber stamp which I planned to use on a large number of manuscripts: "Not read but rejected."



The Physician & The Law

No Negligence in Surgeon's Failure to Supervise Anesthesiologist

THE widow of a patient who died during preparation for a laminectomy sued the surgeon, the anesthesiologist and the hospital. The hospital settled for $20,000 and the anesthesiologist for $210,000 prior to trial. A California jury decided in favor of the surgeon.

The widow contended that the surgeon had negligently failed to supervise the anesthesiologist properly. She further contended that the surgeon failed to administer resuscitation to her husband promptly.

The surgeon contended that supervision of the anesthesiologist was not his responsibility. He said that resuscitation was administered in a timely and proper manner. —*Holquia v. Mission Hospital* (Cal.Super. Ct., Los Angeles Co., Docket No. SEC 10263, Feb. 24, 1975)

Reprinted with permission from THE CITATION published by the Law Division of the American Medical Association.

Questions and Answers

We invite you to submit questions to the Editorial Office, Kahler East, Suite C, Rochester, Minnesota 55901. The names of those submitting questions will remain anonymous if so desired.

The answers will be prepared by competent authorities, and their names will or will not appear, according to their specific wishes.

QUESTION: *Atropine up to 0.6 mg given as premedication to patients with glaucoma is usually considered not harmful, because of its small amount. During the process of reversal of nondepolarizing muscle relaxants, atropine is frequently given in conjunction with antagonists in doses of 1.5 mg or 2 mg. Is this considered safe?*

MD, Ohio

ANSWER #1: Atropine has long been incriminated as an anticholinergic agent responsible for the production of angle-closure glaucoma when administered systemically, with very little substantiating evidence.[1] Certainly, topical atropine, by increasing pupillary block and producing mydriasis, crowding the iris into the predisposed anatomically narrowed angle, can produce angle-closure glaucoma.

Systemic administration of the usual preanesthetic doses of atropine (0.6 mg) has been said to be safe even in anatomically predisposed eyes.[2]

Administration of large doses of atropine in conjunction with the use of prostigmine (or similar drugs) during the process of reversal of nondepolarizing muscle relaxants at varying planes of anesthesia is a much more complex problem. There is an amazing paucity of information regarding pupil size during this process. In the eye with an angle predisposed to develop angle-closure glaucoma, any mydriasis may precipitate an attack of angle-closure glaucoma. Rosen[3] feels that the dangers are mythical. He compares the amount of systemically administered atropine reaching the eye to the amount available to the eye with the administration of a single drop of 1% atropine solution topically. Extending his calculations for 2 mg of atropine given systemically and evenly distributed in a 70-kg individual, only 0.0004 mg reaches the entire eye as compared to 0.6 mg of atropine available to the eye when a single drop of a 1% solution is applied to the eye.

Practically, the fear of producing an attack of acute angle-closure glaucoma can be dispelled by administering topical pilocarpine solution (2%) to produce miotic pupils preatropinization[4] or using morphine as a preanesthetic agent, which also produces a profound miosis. In any patient with known glaucoma, either angle-closure or open angle, continuation of glaucoma medication before, during, and after operation is advised. In the recovery room, an evaluation of the pupils with respect to size, symmetry, and shape would confirm the absence of angle-closure glaucoma. If the pupils are irregular, asymmetric, and mid-dilated, an ophthalmologic consultation should be obtained to medically control and eventually surgically correct the attack of angle-closure glaucoma.

ANSWER #2: *Atropine* in these doses would tend to dilate the pupils and paralyze the ciliary muscle. *Neostigmine* has the opposite effect, tending to constrict the pupil and cause the ciliary muscle to contract. Where the balance might lie between these two antagonistic actions would determine the resultant total effect on pupil and ciliary muscle. It would be interesting to have data from observations on patients under these special circumstances to determine where the balance generally lies. This could easily be done by measurement of the size of the pupils, and one could estimate that the ciliary muscle was being affected in a similar manner.

In patients with *chronic open-angle glaucoma*, if the balance were far in the direction of dilation of the pupil and paralysis of the ciliary muscle, one should not be surprised if the intraocular pressure becomes elevated, but in this kind of glaucoma and under these special circumstances, one would expect that the amount and duration of elevation of intraocular pressure would rarely be enough to cause permanent damage to the eye. If the patient was receiving antiglaucoma medications, such as miotic eyedrops and systemic carbonic-anhydrase inhibitors, one would expect less elevation of intraocular pressure.

In the great majority of patients with chronic open-angle glaucoma under ordinary treatment, and who do not have far-advanced loss of vision from their glaucoma, one would expect the risk to vision to be negligible, but to establish whether this opinion is valid, a clinical study is needed in which not only the pupils are measured but also the intraocular pressure (by tonometer), and the visual fields before and several days after the procedure, when the effects of neostigmine and atropine were gone.

In patients with chronic open-angle glaucoma, the risk is negligible, but there is a small category of patients in whom the anterior chamber of the eye is abnormally small and shallow anatomically, and who without treatment may maintain normal intraocular pressure. If their pupils are dilated, they may very rapidly develop *acute angle-closure glaucoma*. This form of glaucoma threatens the eye with severe damage and potentially irreversible loss of vision within 2 or 3 days if unrecognized and untreated. Presumably, such patients would be at risk only if the antagonistic effects on the pupil by neostigmine and atropine resulted in noticeably dilating the pupil.

It is difficult to identify people in advance who may develop acute angle-closure glaucoma if their pupils are dilated, but if the anesthesiologist or internist learns to recognize by looking carefully at the depth of the anterior chamber (distance from cornea to iris) with the aid of a small beam of focused light, the chances of identifying these individuals can be increased, and an evaluation by an ophthalmologist can be obtained for the occasional person with conspicuously shallow anterior chambers. Prophylactically, the ophthalmologist may wish to prescribe pilocarpine eyedrops of low concentration and a carbonic-anhydrase inhibitor.

Persistent enlargement of the pupils, and, especially, unequal enlargement and irregular enlargement (so that the pupil is not round) are the foremost basis for suspicion and for tonometric measuring of intraocular pressure. One should not count on the patient to complain about decrease of vision or pain in the eye, since patients in the critical period after anesthesia are notoriously unreliable in recognizing and reporting these symptoms.

QUESTION: *It is well known that food and water pass over the tongue and into the esophagus without triggering the gag reflex. Equally well known is the fact that a foreign object such as one's finger or a laryngoscope blade does trigger the gag reflex when it touches the same portion of the tongue (in the unanesthetized patient).*

Please explain the neuromuscular and other factors that prevent the activation of the reflex in the presence of food, yet cause activation in the presence of a foreign object.

MD, Oklahoma

ANSWER #1: In humans, the areas of maximum sensitivity to the second, or pharyngeal, stage of swallowing are the anterior and posterior pillars of the fauces and the tonsils. The sensory nerve for the pharyngeal stage of swallowing is basically the glossopharyngeal nerve.[1] The areas of maximum sensitivity to the gag reflex are the fauces, base of tongue, palate, and posterior pharyngeal wall. The sensory innervation for the gag reflex is also the glossopharyngeal nerve, with contributions from V and X.[2]

The glossopharyngeal afferent fibers include both fibers that elicit the gag reflex and fibers that inhibit the gag reflex. The inhibiting fibers of the 9th nerve respond to milder stimuli than do those fibers which call forth the gag reflex.[2] Therefore, mild stimuli, such as small amounts of water, salivary secretions, or food, will inhibit the gag reflex and stimulate the second, or involuntary, stage of the swallow reflex. Stronger stimuli, such as accumulated saliva or a large bolus of food, will stimulate the gag reflex. In addition, the gag reflex is influenced by fibers that pass to and from the coordinating center in the medulla oblongata to the cerebral cortex, thus giving rise to the gag reflex secondary to repulsive sights or odors received from the eyes, nose, and mouth.[3] The course of the exact neuropathways from higher centers to the medullary centers is still unclear.[4]

In unanesthetized individuals, cortical influences, as well as the degree of stimulation by a finger or laryngoscope, account for the triggering of the gag reflex. The reflex may be inhibited by asking the patient to quietly breathe in and out, a phenomenon thought to be secondary to respiratory inhibition of the gag reflex via a final common pathway.[2]

ANSWER #2: This question should occur to every anesthesiologist but seldom does, or at least is seldom voiced. It did occur to Wassilieff,[1] who noted on himself that tactile stimulation of the soft palate inhibited swallow, and, in longer continuation, elicited nausea and retching. In the monkey, swallow is found to be alternative to retching as a response to continued stimulation of the superior laryngeal nerve.[2]

As stated by Doty and Bosma,[3] stimulation of afferents in the pharyngeal area is pluripotential, deglutition being but one of several effects obtainable. These authors suggested that such functions as chewing, licking, coughing, sneezing, gagging, and respiration, which overlap in their afferent and efferent channels, may interact with swallowing, but, as expressed by Bosma (personal communication, 1975), swallow and, apparently, the associated feeding composite, so dominate the bulbar area that alternative elicitations are inhibited.

Of cognate interest is the well-established roentgenologic observation[4,5] that when radiopaque liquid is swallowed, a little material frequently penetrates the entrance of the laryngeal vestibule, only to be expelled later by hyperelevation of the larynx against the inverted epiglottis, in a kind of squeeze action. Absence of a cough reflex during this period is usually attributed to the mode of association of the reflex centers of the medulla, which is thought to render the major reflex actions mutually exclusive.[6] The burst of coughing occasionally evoked with a swallow suggests to me that this explanation is not the whole story, and that another mechanism may sometimes also be involved.

A bunched-up appearance at the entrance is observable laryngoscopically in prolonged effort closure of the larynx (complete laryngeal spasm), and probably results in part from inversion of the mucosa by aryepiglotticus muscle fibers ending in the mucosa. In swallow, such inversion removes cough-originating receptors from contact

with vestibular bolus. Incompleteness of the inversion or of the above-mentioned squeezing action could explain a cough triggered at this time.

Finally, cineradiography[4] shows that about 0.5 second elapses between the time the leading edge of a bolus passes the fauces and the time the trailing edge enters the esophagus. If the period of stimulation of gag-originating receptors necessary to elicit a gag reflex exceeded 0.5 second, the apparent suppression of gag by swallow would again be accounted for.

QUESTION: *1. Does the patient have the right to request the Professor of Anesthesiology or one of the senior anesthesiologists to perform the intubation or any other anesthetic procedure rather than one of the professor's students? 2. What are the possible legal consequences following this request?*

MD, Belgium

ANSWER #1: The question relates to the contract for patient care embodied in the physician-patient relationship. Belgium is a civil-law country; my answer is couched in terms of the common law of the USA and countries of the British Commonwealth. The legal principles should be similar, however.

Patients who enter teaching hospitals are under constructive notice that a major portion of their care will be given by trainees, acting under staff supervision. It is common knowledge among the American public (and, I assume among citizens of other countries as well) that a university hospital is engaged in teaching and that house officers and even medical students participate actively in patient care. Thus, if the patient does not request the service of a specific staff physician, it is customary practice to allow residents to perform such tasks as laryngoscopy and endotracheal intubation, as well as to select and administer the anesthetic agent.

If a patient inquires of the staff as to who will be caring for him, he must be apprised frankly and honestly. The patient does have the right to request the services of a staff physician. This is so because the contract for medical care, embodied in the physician-patient relationship, is a personal-services contract. As such, the duties emanating from it cannot be delegated without the express consent of the parties. If a physician unilaterally delegated to others any of his duties to the patient, especially to someone less skilled than he, he could be liable for fraud or breach of contract. The delegatee could also be liable for battery, since he performed a service that the patient had not authorized him to carry out.[1]

As with many other aspects of medical care, absent emergency circumstances, it is highly desirable that the patient's wishes be followed.

Cleveland, Ohio

* * *

ANSWER #2: The answer to the first question is yes; to the second, the professor, qua physician, ignores his patient's requests at his financial peril.

The fact situation falls within the Anglo-American Common Law doctrine of Consent (conversely, assault and battery). Each individual has the right to designate who may touch him and to what extent. This right to bodily integrity is not only nearly absolute but is also jealously guarded by the courts.[1] The patient's right to bodily integrity lets him choose both who may and may not

administer anesthesia to him (and intubate his trachea), either implicitly or explicitly.

If the professor, qua the patient's personal anesthesiologist, lets the student intubate his trachea against the patient's explicit request to the contrary, the student is guilty of a battery (an unlawful touching). If uninjured, the patient-plaintiff is entitled to nominal money damages. If injured, the patient is entitled to compensatory money damages commensurate with the injury. If the patient-plaintiff's rights were willfully and wantonly abused, punitive damages can also be awarded—often 3 times the compensatory damages. If the professor helped (touched), the same analysis applies.

On the other hand, if the professor watched as the student intubated the patient-plaintiff's trachea, the patient would be hard pressed to allege and prove that the professor committed a battery. However, the professor can probably be sued successfully under several other legal theories: negligence; abandonment; fraud and deceit; contract.

"Negligence" requires the patient-plaintiff to have been injured. The gist is: The professor had the duty to do the intubation himself or turn it over to a competent anesthesiologist; the professor did neither; as a direct result, the patient was injured. The professor pays.[2]

The gist of abandonment is that, because the patient-physician relationship has been established, the professor, qua physician, has the duty to personally care for (intubate) his patient. The professor breached that duty to the patient's detriment.

"Fraud and deceit" requires the patient-plaintiff to prove that the professor led him to believe that he would do the intubation, while all the time, the professor intended and knew the student would do it.[3]

Under a contract theory, the patient-plaintiff must allege and prove that the professor made an oral contract to personally anesthetize (intubate) the patient; that the professor did not do so. The patient-plaintiff is, therefore, entitled to damages for breach of contract.

the book shelf

Paediatric Anaesthesia, Second Edition—Davenport, Harold T., MB, FRCP(C), FFARCS. Chicago, Year Book Medical Publishers, Inc, 1973, 258 pp.

This monograph has been written by an anesthesiologist with great clinical experience in pediatric anesthesia. Short and easily readable, this book encompasses a broad overview of the subject.

Some of the contents seem too basic: drawings of venipuncture technics, for example. However, the chapter entitled "The Child Patient" is particularly well done and should be of interest to any anesthesiologist who deals with children. The physiologic and physical differences of the pediatric as compared with the adult patient are briefly but well summarized.

Anesthesia for major operations and for patients with rare conditions is dealt with quite superficially. An anesthesiologist would likely find this book only a starting place were he to deal frequently with major pediatric cases.

This book could be of interest to anesthesiology residents and as a refresher for those who care for pediatric patients on a limited basis.

Treatment of Pain—Voris, Harold C., MD, PhD, and Whistler, Walter W., MD, PhD, Editors. Springfield, Charles C Thomas Publishers, 1975, 161 pp, price $14.00.

The editors of this book have assembled a number of presentations on the treatment of chronic intractable pain. The presentations were made at a pain-treatment symposium sponsored by the Department of Neurological Surgery, Rush Medical College, Rush-Presbyterian-St. Luke's Medical Center, Chicago. The contributors are noted authorities on the current practices of treating chronic pain problems.

Although the book is primarily oriented toward the surgical technics of pain management, other modalities such as acupuncture, hypnosis, and drug therapy are also covered.

The material presented in this book is easily readable and understandable. The information presented will be beneficial to anyone interested in the clinical management of chronic pain problems.

Fluids for Anesthesia and Surgery in the Newborn and the Infant—Bennett EJ. Springfield, Illinois, Charles C Thomas, Publisher, 1975, 205 pp, price $18.50.

This comprehensive book should fill a long-standing void in the field of pediatric anesthesia. Dr. Bennett and contributors, Drs. Dalal, Ramamurthy, and Schmidt, have done an outstanding job in writing it.

Chapter 2, "The Newborn," is alone worth the price of the book. Dr. Bennett details what is known about neonatal renal function and various fluid regimes that have been proposed to meet the needs of the neonate. This is a controversial area and

the question of the quantity and especially the electrolyte content of fluids to be administered has long been debated. Dr. Bennett very logically presents the facts that:

1. The neonatal kidney is quite mature in its function and

2. Can concentrate urine and

3. Fails to conserve sodium in the presence of a sodium deficiency.

With this in mind, he gives a rationale for the use of multielectrolyte solutions in the neonate.

Although the book contains only 205 pages, it is extensive in its coverage of the subject. Readers will find a most complete chapter on pyloric stenosis and the ramifications of fluid therapy in this commonly encountered entity. Other problems, including omphalocele, ruptured bowel, colostomy, congenital diaphragmatic hernia, to name but a few, are also covered succinctly, if not as completely. The chapter on intravenous alimentation, by Dr. Ramamurthy, should be especially interesting to pediatric anesthesiologists, who are usually not concerned with this technic and its problems.

The book is to be recommended to all interested in pediatric anesthesia. However, the reader should not plan to get through it quickly, as a large amount of detail is covered. It should be of help to all who care for neonates and infants, both intraoperatively and perioperatively.

Acupuncture Anesthesia (A Translation of a Chinese Publication of the Same Title). Miami, U.S. Directory Service, 1975, 340 pp, price $30.00.

Acupuncture analgesia (not anesthesia) has been practiced in China for a number of years with varying degrees of success. The original Chinese text was prepared by several investigators and practitioners in Shanghai. It consists of historical backgrounds, empirical technics of acupuncture analgesia for various surgical procedures, and speculation on the hypotheses of mechanism of action.

The difficulties of acupuncture analgesia include unknown mechanisms, lack of standard technics, and inconsistent results; it is an interesting procedure and may have some practical value in extremely rare instances.

Information in the book is believed reliable, but its accuracy and completeness should not be accepted without additional data obtained from further scientific investigation. It is hoped that the book will lead to further investigation and a better understanding of the subject.

Electroanesthesia: Biomedical and Biophysical Studies—Sances, Anthony, Jr. and Larson, Sanford J. New York, Academic Press, 1975, 367 pp, price $36.00.

Recently, considerable evidence has been accumulated to demonstrate the clinical usefulness of electroanesthesia in man. In the authors' laboratory, more than 2000 applications of electroanesthesia have been given the monkey.

The text consists of the authors' observations on different technics of electroanesthesia and its effects on various physiologic parameters, experiences of electroanesthesia in man, and chapters prepared by investigators in India, Japan, and Russia. While the optimal waveform and currents have not yet been established, it has been shown that various types of diffuse time-changing electric currents applied transcranially via external electrodes can produce unresponsiveness in experimental animals, permitting major surgical procedures without other anesthesia.

The authors have reported much information in a well-organized manner. This book will lead to further investigation and a better understanding of electroanesthesia.

PNEUMATOCELE OF THE LARYNX: A COMPLICATION OF PERCUTANEOUS TRANSTRACHEAL VENTILATION—Edward Carden, M.B., FRCP(C), and Thomas C. Calcaterra, M.D., Los Angeles, California.

EVALUATION OF LARYNX AND TRACHEA BY XERORADIOGRAPHY—S. S. Moorthy, M.B., B.S., Alvin M. LoSasso, M.D., Harold King, M.D., and Edmund Franken, M.D., Indianapolis, Indiana.

A Guide for Authors

Anesthesia and Analgesia . . . Current Researches invites original manuscripts on subjects pertinent to the specialty of anesthesiology. Original articles accepted for publication, or papers presented at the Society's annual scientific meetings which subsequently may be published in the Journal, become the property of the International Anesthesia Research Society. Reproduction in whole or in part is not permitted except by written consent of the publisher and the author.

Submit manuscripts in triplicate to—
T. H. Seldon, M.D., Editor
Kahler East, Suite C
Rochester, Minnesota 55901, U.S.A.

All papers are reviewed by the Editorial Board and other selected referees. If accepted for publication, editorial revisions may be made to aid clarity and understanding without altering the meaning. Edited copy is submitted to authors for approval before it is sent to the printer. Page proof will be submitted to authors for final approval. Reprint order forms will accompany page proof.

Titles should be concise but informative, with thought given to the use of key words for indexing. Ninety characters, including punctuation and spaces, should be sufficient.

Coauthors' names should be followed by the major degree, professional affiliation, and address.

Abstract: On the first page of manuscript, an abstract of from 50 to 250 words, according to length of article, but not exceeding one double-spaced typed page, should describe purpose, methods, results, and conclusions, as succinctly as possible. This replaces both former Capsule Review and Summary, but is the same in content and format.

Type manuscript (in triplicate) on 8½ x 11-inch white paper, with 1½ inch margins at top, bottom, and both sides. Double space ALL typing, including references, legends and footnotes.

References: About 20 references are acceptable. In extensive reviews of the literature, readers will be advised that longer reference citations can be obtained from author. Citations should include (1) last name of author followed by initials without internal punctuation; (2) commas separate names and initials of authors; (3) four or more authors are designated as "et al;" (4) journal name is abbreviated according to Index Medicus style; (5) references from books show (a) city of publication, name of publisher, date of publication, after book title; (6) journal references give volume, first and last page numbers, year. (See previous issues of *Anesth & Analg* for style.)

Tables should be self-explanatory and should supplement, not duplicate, the text.

Photographs should have sharp contrast, be on *glossy* paper unmounted, and 4 by 5 inches or larger. *Polaroid prints damage easily in handling and thus may reproduce indistinctly. Glossy prints are preferred.* Submit photographs of roentgenograms with contrasts as in original and sharply defined; "TOP" must be identified. All illustrative materials, charts, etc., must be submitted in triplicate, clearly numbered according to text and legend.

Lettering on charts and graphs must be large enough to be legible when reduced in size. Curves, scatter dots, etc., should contrast with reference lines.

Drawings must be in black (India) ink on white background and should be of professional quality.

Legends for illustrations should be concise and typed on one page. Legends for photomicrographs should show stain and magnification data.

Drug names used in the text should be generic unless trade names are essential to the discussion.

Multiple Publication: To avoid violating existing copyrights, a statement should accompany each submitted article indicating that the material in question:

1. Has not been simultaneously submitted to another journal.
2. Has not been previously published elsewhere.

a. Abstracts of 400 words or less do not constitute prior publication.

b. A report issued by requirement of a governmental agency or comparable granting institution does not constitute prior publication.
